MORAT, Jacques ('09), Mgr., Fdy. Dept., M. Berliet, Venissieux; *for mail,* 3 Allée Ronsard.

VILLEFRANCHE-SUR-MER, Alpes-Maritimes

GARNIER, Alphonse ('29), Life-Member; Member, Bd. Directors, Cie. de Fives-Lille, 7 rue Montalivet, Paris; *for mail,* Villa "Dianina," Villefranche-sur-Mer.

GERMANY

AACHEN

LANGER, Paul ('24), Prof. M. E., Technische Hochschule.

AIX LA CHAPPELLE

WALLICHS, Adolf ('08), Prof. M. E., Tech. Univ. of Aix la Chapelle, Nizza Allee 65.

BERLIN

FITZGERALD, John W. (J'28), John McMullen Research Scholar, Sibley College, Cornell Univ., Ithaca, N. Y.; *for mail,* Dresdner Bank, Berlin, Germany.
HERPEN, A. Theo. ('25), Managing Dir., Steam Boilers & Power Plants, Gesellschaft für La Mont Kessel und Kraftwirkschaft, m. b. h., Schadowstr. 1 b, N. W. 7.
HEYERDAHL, Thorvald ('12), Export Mgr., S. A. Ferrum, Katowice, Poland; *for mail,* Neue Grünstr. 18, Berlin, S. W. 19, Germany.
MATSCHOSS, Conrad ('13), Life Member for Distinguished Service, '13; Prof., Mem. of Council Verein deutscher Ingenieure, 27 Hermann Goering Str.
MUNZINGER, Friedrich ('25), Dir. Allgemeine Elektricitäts-Gesellschaft, Friedrich-Karl-Ufer 2/4, N. W. 40.
NEUHAUS, Fritz ('98; '06), 33 Pariserstr., W. 15.
QUEISSER, H. W. ('28; '34; '35), M. E., Siemens-Schuckertwerke A. G.; *for mail,* Jungfernheideweg 10, Berlin-Siemensstadt.
SCHULZ, E. ('26; '35), Duesseldorferstr. 19/20. W. 15.
STUMPF, Johann ('96), Privy & Govt. Counselor, Kurfurstendamm 33, W. 15.
TATARSKY, Geo. F. (J'31), M. E., Allgemeine Elektricitäts-Gesellschaft, Friedrich-Karl-Ufer 2/4, N. W. 40.
ZUR NEDDEN, Franz ('29), Secy., Charge Tech. Committee, Reichskohlenrat, Pariser Str. 44, W. 15; *for mail,* 28, Prager Str., W. 50.

BLANKENESE-ELBE

DUENSING, Heinrich F. A. ('26; '35), Teacher of Matls. Handling, Technology, Höhere Technische, Staatslehranstalten, Hamburg, Luebecker Tor, Hamburg; *for mail,* Zur Fernsicht 15, Blankenese-Elbe.

BREMEN

BLAUM, Rudolf ('30), Dir., Atlas-Werke, A. G., Stephanikirchenweide.

CHARLOTTENBURG

FROELICH, Friedrich Carl ('13), Cons. Engr., Adolf Hitler-Platz 8, Charlottenburg 9.

DARMSTADT

VOIGT, Heinz ('26), Prof., Technische Hochschule; *for mail,* Hobrechtstr. 28.

DRESDEN

HANKE, Walter (J'33), An den Kalkoefen 17, Dresden-Reich.

HAMBURG

PETERS, Claudius ('30), Pres., Claudius Peters, Glockengiesserwall 2, Hamburg 1.
SCHUETZ, Werner V. ('27), Sophienstr. 24, Hamburg 4
VON SCHOENAICH, Stephan F. ('28; '35), Sales Engr., Deutsch-Amerikanische Petroleum Gesellschaft, 21 Neuer Jungfernstieg, Hamburg 36; *for mail,* 65A, Magdalenenstr., Hamburg 13.

HEIDENHEIM

LANG, Richard T. ('25), Tech. Dir., J. M. Voith Maschinenfabrik, Heidenheim/Brenz.

KARLSRUHE

STREETER, Victor L. (J'35), Kornbloomstr. 1.

LEIPZIG

BRANDT, Franz ('29), Helfferichstr. 50, Leipzig C 1.

MAGDEBURG

KLEIN, Otto Karl ('27), Gen. Mgr., Schaeffer & Budenberg.

MANNHEIM

KÖLSCH, Otto ('25), Tech. Dir., Heinrich Lanz, Aktiengesellschaft, Lindenhofstr.

MUNICH

HEALY, Geo. W. (J'33), Tuerkenstr. 58.
MAYR, Karl A. ('27; '35), Pat. Atty., 90 West St., New York, N. Y.; *for mail,* Maximilianstr. 20b, Munich, Germany.
THOMA, Dieter ('25), Prof., Technische Hochschule; *for mail,* Nordliche Auffahrtsallee 23, Munich 19.

NEUSS

SCHAURTE, Werner T. ('27), Pres., Bauer & Schaurte.

ROTTACH-EGERN

FALIAN, Curt L. ('31), Landhaus Nr. 81, Rottach-Egern, Oberbayr.

SCHWELM

GRIESENBECK, Wm. (J'27), Wks. Mgr., G. Griesenbeck, Bahnhofstr. 41, Schwelm, Westfalen.

STUTTGART

NESTEL, Hermann A. (J'27), c/o Betriebstech-Landesgewerbemuseum, nische Ausstellungen.
SCHUETZE, Gerhard (J'30), c/o Robert Bosch A. G., ZW/WZE.

GREAT BRITAIN

England. See Page 164

Ireland. See Below

Scotland. See Page 166

GREECE

ATHENS

FLORAS, Christos L. (J'28), Prof. & Dir., Charge Sanitary Engrg. Sch. of Hygiene, Ministry of Hygiene; *for mail,* 9 Lefkossias St.

HOLLAND

See (The) Netherlands, Page 166

IRELAND

BELFAST

ALEXANDER, David H. ('28; '34), Prin., College of Tech.; *for mail,* 606 Antrim Rd.

ITALY

BRESCIA

MARZOLI, Luigi (J'08), Gen. Mgr., Supt., Fratelli Marzoli, Palazzolo s/Oglio.

FINALE LIGURE

CASIRAGHI, Giovanni P. ('28; '34; '35), Ch. Engr., Tech. Dir., Piaggio & Cie.

FLORENCE

FOSTER, Ernest H. ('85; '94), Villa la Colombaia, Via Marignolle 2.

IVREA

OLIVETTI, Adriano (J'26), V. P., Gen. Mgr., Ing. C. Olivetti & C. S. A.

MILAN

CATTANEO, Giustino ('30), Ch. Designer for Aero. Eng. & Lorries, S. A. Alfa Romeo, via M. U. Traiano 33; *for mail*, 32 Via Leopardi.
REGGIORI, Alessandro (J'35), Research Engr., Societa Italiano Ernesto Breda.

RIVOTELLA DEL GARDA

ANDREI, Camillo ('11; '26).

ROME

PERRONE, Pio (H'20), Grande Ufficiale Ing., Via Pinciana Nuova 36.

TERNI

ALBERTI, Alforisio ('35), Gen. Dir., Steel Plants, "Terni" Societa per l'Industria e l'Elettricita, Viale Brin.

LITHUANIA

KAUNAS

GRAICUNAS, V. A. ('24; '33), Mgmt. Consultant, Ordnance Dept. & Military Aviation; *for mail*, Vaižganto g-vė 12 but. 7.

(THE) NETHERLANDS

AMSTERDAM

BLICKMAN, John A. ('14), Mem. Firm, Koopman & Co., Stadhouderskade 6.
CHORASO, Z. (J'32), Engr., Charge Stress Analysis, N. V. Nederlandiche Vliegtuigenfabrich Fokker, Amsterdam Naviel; *for mail*, c/o Dr. E. Schatzki, Minervalaan 82hs, Amsterdam, Zuid.
REYDON, Henry (J'30), c/o Dr. J. Smit, 12 Minerva Laan.
VERKOZEN, A. J. (J'31), Cons. Mgmt. Engr., Joh. Verhulstraat 91.

HAARLEM

JULIUS, M. A. ('31), Ch. M. E., Joh. Enschedé en Zonen, Graf. Inrichting N. V., Klokhuisplein 5.

STUDENT MEMBERS

THE following roster of names of Student Members of The American Society of Mechanical Engineers, grouped under the Student Branches to which they belong, was the complete list on file at the Society headquarters on January 1, 1937.

University of Akron

- Alexander, A.
- Brubaker, F. A.
- Buchtel, K. A.
- Cornell, D. H.
- Fretz, G. C., Jr.
- Fuller, C.
- Good, J. F.
- Groney, C. W.
- Harper, T. C.
- Harris, J.
- Kolk, C.
- Kovach, J. I.
- Levin, S. L.
- Martin, J. E.
- Orr, G. H.
- Roppel, J. G.
- Rottmayer, E.
- Saus, F. J.
- Taylor, E. R.
- Vukan, F. S.
- Weaver, T. C.

Alabama Polytechnic Institute

- Bagby, F. K.
- Bodden, T. R.
- Briggs, E. W.
- Burrus, G. J., III
- Collins, G. J., Jr.
- Crumbaker, M. O.

The Prevention of Failures of Surface-Condenser Tubes

By R. E. DILLON,[1] G. C. EATON,[2] BOSTON, MASS., and H. PETERS,[3] CAMBRIDGE, MASS.

This paper describes the developments in the prevention of failures of surface-condenser tubes in the steam-electric generating stations of The Edison Electric Illuminating Company of Boston. The authors apply the latest theories of destructive cavitation to show that the inlet-end wastage of tubes in a single-pass condenser is the result of vortices in the inlet water box. These vortices result in destructive cavitation which starts when the water pressure at a point approaches the pressure corresponding to the water temperature, and the cavities in the water are filled with vapor. When the existence condition for the vapor disappears through increase of pressure, the vapor bubbles condense and very high impacts on adjacent surfaces result. Tiny particles are broken from the surface by repeated impacts, making larger and larger pits, and eventually holes through the tube are produced. Guide vanes installed in the inlet water box of the condenser have effectively prevented the vortices from forming.

SINCE the early years of this century, the steam-electric generating stations of The Edison Electric Illuminating Company of Boston have been the testing ground for surface condensers. With the full knowledge that the surface condenser can be the source of a major yet preventable loss of power-plant efficiency, the engineers of this company have been indefatigable in their efforts to develop and apply practical ways and means of keeping surface-condenser tubes clean and to increase the economic life of the condenser tubes themselves. It is with the second of these endeavors concerning surface condensers that this paper deals.

Some 25 years ago, in cooperation with the condenser-tube manufacturer who developed the process, tubes of Admiralty metal made by the cup-drawn method were tried out in the surface condensers serving the vertical turbines in the early section of the L Street Station in South Boston. Steam at 200 lb per sq in., and 500 F operate these turbines. The results of the early experiments and developments were very gratifying. Dezincification and consequent tube failures sharply decreased. A large portion of the Admiralty tubes installed at that time are still in service due to developments which will be discussed in this paper.

With the reduction of dezincification, the phenomenon of inlet-end wastage of condenser tubes was made more pronounced. It was noted that this wastage was concentrated within the first few inches. Since the tubes were packed with corset lacing and ferrules, the use of longer or extended ferrules was tried in the hope of confining the wastage to the replaceable ferrule. Moderate success was achieved by this method.

The replacement of extended ferrules, while much cheaper than tube renewal, was nevertheless expensive. The idea of lining the inlet end of the tubes with a bushing which could be easily inserted and readily replaced was conceived and developed (see Fig. 1). An effort was made to conform the inside surface of the bushing to the shape of the vena contracta in order to remove at this point the turbulence and high vacua with consequent air liberation from the circulating water. This turbulence and air liberation were at that time blamed for the inlet-end wastage of the tubes.

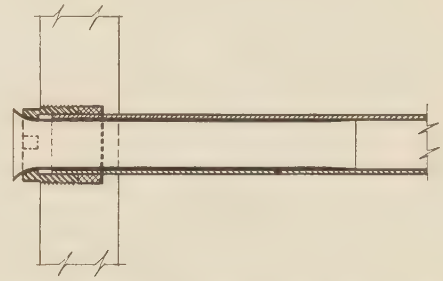

Fig. 1 Bushing Inserted in Tube Packed With Corset Lacing, Fiber Washer, and Screwed Ferrule

The inlet-end bushing was a pronounced success and a major step in the prolongation of tube life. There was but one detrimental effect of the use of the bushings upon the condenser tubes themselves. The tapered or downstream end of the bushing (see Fig. 1) cannot be made infinitely sharp or to fit exactly the inner surface of the tube. As the result of these practical limitations, there is an irregularity or shoulder in the combined inner surface of bushing and tube, *after* which minor tube wastage usually occurs. This effect upon the tube has been minimized by installing subsequent bushings of increased length to cover the slightly wasted portion of the tube. The bushings have invariably required replacement before the tube wastage at this point has become serious.

[1] Superintendent of the Generating Department, The Edison Electric Illuminating Company of Boston. Mr. Dillon was graduated from Massachusetts Institute of Technology in 1910. After six months with the North Packing and Provision Company, he entered the employ of the Edison Electric Illuminating Company of Boston and before promotion to his present position was successively head of the Steam and Chemical Division of the Standardizing and Testing Department, technical engineer, and assistant superintendent in the department he now heads.

[2] Head, Mechanical Technical Engineering Division, Generating Department, The Edison Electric Illuminating Company of Boston, Jun. A.S.M.E. Mr. Eaton was graduated from Harvard College in 1923, and from the Harvard Engineering School in 1925. Since 1925 he has been employed as a mechanical engineer in the division he now heads.

[3] Assistant Professor of Aeronautical Engineering, Massachusetts Institute of Technology. Dr. Peters received his Dipl. Eng. degree from the Technische Hochschule of Darmstadt, in 1925, and his Dr. Eng. degree from the Technische Hochschule of Munich, in 1930. For five years he was assistant at the Kaiser Wilhelm Institut für Stromungsforschung. In 1931 he became Research Associate at the Massachusetts Institute of Technology, where in 1935 he was advanced to his present position.

Contributed by the Power Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

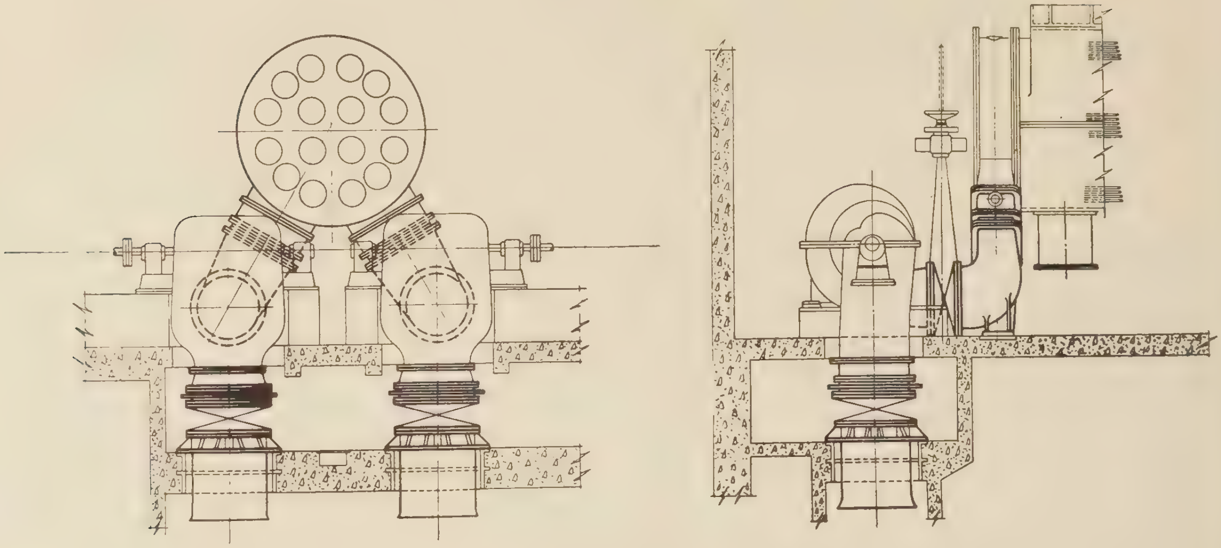

Fig. 2 Single-Pass Condenser With Pumps and Connected Inlet Piping as Installed at the Edgar Station

The problem of tube cleaning when bushings are installed has been successfully solved by the use of bristle brushes six to eight tube diameters long. These brushes are inserted at the inlet end of the tube and "shot" through the tubes by a "gun" admitting a turbulent mixture of water and compressed air behind the brush.

Single-Pass Condenser

The first single-pass condenser to be installed in a Boston Edison station was placed in service in 1927, and soon after it was equipped with bushings. Until this installation, only two-pass and four-pass condensers were in use at the L Street and Edgar Stations. The life of the tubes in these multipass condensers was entirely satisfactory and has continued to be so after the installation of the bushings previously described. The new single-pass condenser required complete retubing in 1932 after but five years of service. The necessity of this retubing had until the last two years been attributed very largely to the unsuccessful use of an inferior type of chlorinating equipment for treating the circulating water to inhibit slime formation in the tubes. Subsequent experience with the second set of tubes has shown that undue weight was given to the effect of improperly used chlorine gas on the first set of tubes, although there is no question but that its use materially hastened tube replacement.

Search for Methods of Eliminating Air Liberation

The very early failure of a considerable number of the second set of tubes near their inlet ends but beyond the downstream ends of the bushings caused the engineers to renew their search for causes of tube failure.

In order to observe and to understand more clearly the conditions existent on the water side of the condenser, observation windows were installed in four access doors of the inlet water box together with adequate illumination. Two of these windows were located just above the horizontal center line of the water box and the other two near its top. Observations through these windows showed that in the upper third of the water box there was a highly turbulent mixture of from very large to very small air bubbles and water. Also in this upper third of the water box, for long and for short periods of time and sometimes almost continuously, long ribbons of air surrounded by a spinning mass of air-bubble-and-water mixture would run from the mid-portion of the water box to the tubes.

Fig. 3 Tubes Removed From Single-Pass Condenser During Four Years of Operation

Attempts to reduce the air liberation had of necessity to be confined to the reduction of minor turbulence in the water box and connected inlet piping, pumps, and intake tunnel. Irregularities in the inside surfaces of these passages were removed or smoothed wherever practicable, the pump impellers and casings were checked for exact alignment, and air leakage at the packings was minimized. The inlet tunnel was vented to insure that no accumulation of air would form near its roof to be drawn at intervals into the pump suction lines. Vertical baffles of various lengths attached to the braces in both inlet and discharge water boxes were tried in an attempt to reduce the surging that was also observed. Two circulating-water pumps were used instead of the usual one to reduce velocities with the accompanying turbulence and air elimination.

These efforts brought little or no improvement in the observed conditions, and tubes failed in increasing numbers. Thus, it

became increasingly clear to the engineers that with the existing arrangement of water box, connecting piping, and pumps shown in Fig. 2, no small changes would reduce the air liberation then believed to be the sole cause of the tube failures. Causes other than air liberation were then looked for in the hope of solving the acute problem without redesigning the existing equipment. In this connection the cavitation experiments at the Massachusetts Institute of Technology were investigated.[4]

Cavitation and Corrosion

A study of the location of the tube failures had already indicated that there were two areas where the percentage of tube failures was relatively much higher than in the remainder of the tube bank. One of these was in the upper-left lobe and the other slightly to the right and below the center of the tube sheet, as viewed from the entrance end of the tubes. These locations are indicated in Fig. 3. Also the damage to the individual tubes was found to occur at the end of the bushings and extending a short distance downstream. The bellmouth entrances to the bushings showed a general thinning nearly equal all over the tube bank, while the divergent part was worn most in the areas of greatest tube failure. The localization of the tube and bushing damage is most reasonably explained as the result of destructive cavitation followed by corrosion. To produce destructive cavitation, the water pressure at a point must approach the vapor pressure corresponding to the water temperature, so that cavities in the water

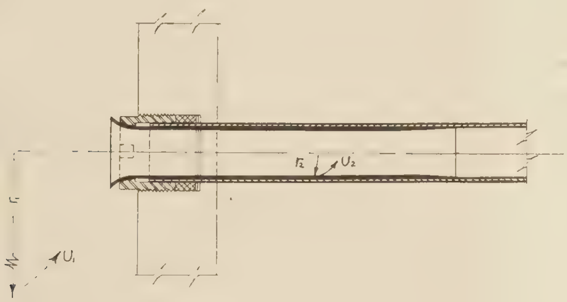

Fig. 4 Water-Box and Tube Velocities for Rotating Flow

are filled largely with vapor. If the existence condition for the vapor disappears through increase of pressure, the vapor will condense or collapse, and an exceedingly high pressure will occur due to the impact of the water filling the vapor space from all sides. Destructive cavitation on any surface will break tiny particles from that surface thus making pits. These pits are well adapted for the accumulation of oxides and salts beneath which a rapid attack may proceed, furthered by the ready supply of oxygen from the liberated air. If this hypothesis, which is readily applicable to a condenser tube, were correct, it would then be desirable to prove the actual possibility of destructive cavitation in the single-pass condenser.

Moody and Sorenson[5] have very definitely proved that cavitation will occur when

$$v_2 = \sqrt{[2g(h_1 - h_2)]} \quad \ldots\ldots\ldots\ldots [1]$$

where v_2 = axial velocity, fps; g = acceleration due gravity; h_1 = static pressure, ft of water; and h_2 = absolute vapor pressure corresponding to the water temperature, ft of water.

If, in a top tube of the single-pass condenser at low tide, h_1 = 12 ft, g = 32 fps per sec, and h_2 = 0.7 ft at 70 F, then the minimum axial velocity v_2 for cavitation to occur will be 26.9 fps. Study of the hydraulics of the condenser show such velocities

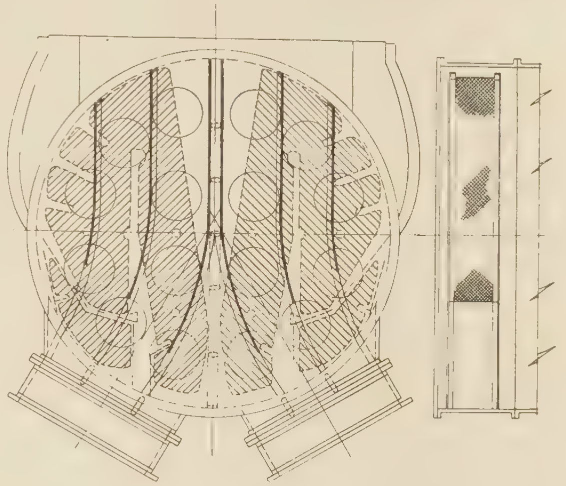

Fig. 5 Guide Vanes Installed in the Inlet Water Box of the Single-Pass Condenser at the Edgar Station

axial to the tubes to be impossible. However, cavitation can easily occur if the water flow in the water box has *tangential* velocity components. Actual observation of the flow had shown tangential-velocity components of appreciable magnitude. The ribbons of air previously referred to were the cores of the vortices and indicated the low pressures existent to release the air.

Referring to Fig. 4 which shows the relative positions of the rotating flow in the water box, a bushing, and tube, the tangential velocities and the radii bear the relation

$$u_1 r_1 = u_2 r_2 \quad \ldots\ldots\ldots\ldots [2]$$

and Bernoulli's theorem gives the pressure-velocity relation

$$h_1 + \frac{u_1^2}{2g} = h_2 + \frac{u_2^2}{2g} + \frac{v_2^2}{2g} \quad \ldots\ldots\ldots\ldots [3]$$

where u_1 = tangential velocity at r_1 of the free vortex in the water box, fps; u_2 = tangential velocity at r_2 of the free vortex in the bushing, fps; r_1 = radius of the vortex in the water box, ft; and r_2 = sectional radius of the bushing, ft.

Solving Equations [2] and [3] for u_1 gives

$$u_1 = \sqrt{\left[\frac{\left(h_1 - h_2 - \frac{v_2^2}{2g}\right) 2g}{\left(\frac{r_1}{r_2}\right)^2 - 1}\right]} \quad \ldots\ldots\ldots\ldots [4]$$

For the hydraulic conditions existent in the condenser, u_1 at a radius of 1 ft would have to be of the order of 0.5 to 1.0 fps to produce cavitation,[6] i.e., yield h_2 equal to the vapor pressure. Such tangential velocities have been observed repeatedly. Cavitation, therefore, exists and appears in the divergent part of the bushings, but the collapse occurs downstream therefrom in the

"Progress Report on Cavitation Research at Massachusetts Institute of Technology," by J. C. Hunsaker, Trans. A.S.M.E., vol. 57, October, 1935, paper HYD-57-11, pp. 423–424.

[5] "Progress in Cavitation Research at Princeton University," by Lewis F. Moody and Alfred E. Sorenson, Trans. A.S.M.E., vol. 57, October, 1935, paper HYD-57-12, pp. 425–428.

[6] Equation [4] reverts directly to Equation [1] when the tangential velocity u_1 of the vortex in the water box is zero, then $[h_1 - h_2 - (v_2^2/2g)] = 0$. Solving for v_2 gives $v_2 = \sqrt{[2g(h_1 - h_2)]}$, that is, Equation [1].

bushings and tubes. The relatively low pressure level and the resultant release of air have a damping effect on the action and prevent the pressure from reaching as high a value in the moment of collapse of the vapor cavities as would otherwise be possible. The cavitation effect, however, will be sufficiently strong to destroy possible protective films. The liberated air, then, will accelerate the oxidation, especially when compressed in the moment of cavity collapse.

The Prevention of Cavitation

From the foregoing theoretical analysis, the next step was to prevent the formation of the vortices with their damaging tangential-velocity components in the condenser itself and the resulting cavitation and tube failures. The rotation of the water to form these vortices was effectively stopped by running two circulating pumps at reduced speed and guiding the flow from the two entrances by vanes located as shown in Fig. 5. The vanes were made from brass angles and $^1/_4$-in. mesh, 16-Bwg Admiralty metal screen. These guide vanes have effectively eliminated the vortices without increasing the pressure drop across the condenser. The authors are confident that time will prove the effectiveness of the guide vanes in reducing tube losses.

Analysis and Tests on Hydraulic Circuits of Surface Condensers

By G. H. VAN HENGEL,[1] DETROIT, MICH.

Illustrated by actual test results, this paper deals with an analysis of hydraulic circuits of surface condensers. The losses in the tubes, condenser water boxes, and piping are treated in detail. The importance of the weir losses in the outlet box is demonstrated. Tests on condensers with and without a weir show the actual gain in hydraulic efficiency obtained without a weir. An exact method is given for the calculation of the liberated air in determining the hydraulic-circuit losses. Since the amount of air liberated governs the rate of corrosion of the tubes, this calculation is of considerable importance, especially for salt-water conditions.

THE PATH of flow followed by the cooling water in passing through the hydraulic circuit of a surface condenser is a long one. The losses due to flow of the water can be separated, for calculation, into (*a*) the canal losses, (*b*) the tube losses, and (*c*) the condenser piping and water-box losses, the latter including the outlet-box weir loss.

These losses, which will be dealt with subsequently in this study, show that the losses of the weir in the outlet box play a large rôle in the total head loss through a condenser, and that the greatest improvement in the hydraulic circuit can be made by omitting the weir.

A way of calculating the air liberated from the circulating water at any point in the system will be described, and from this the siphon loss will be deduced. The importance of this calculation is for determining the venting of the circulating-water circuit and the possibility of tube corrosion and its prevention.

The Calculation of the Losses in a Hydraulic Circuit

(*a*) *Canal Losses.* Before the circulating water serves its function of cooling in the condenser, it must be pumped from the river or storage reservoir, and to this source it must also be returned. The connection between the cooling-water source and the condenser is furnished by the canal tunnels. For the highest load, the goal should be a maximum loss of 1 ft, including the losses through the trash rack and screens. Naturally, if more than one condenser is served by the same intake and overflow canals, this loss will be somewhat larger. Economic reasons will determine how high it actually can be. The screens form most of the canal losses, and adequate attention should be given in the design to keep the velocities as low as possible through these screens. Even then they cause high losses if not cleaned frequently. They are usually clogged most in the late summer from leaves, grass, and fish, when a great quantity of water is still demanded for cooling.

Attention should be given to the fact that air liberated in the intake tunnel from swirling should have an opportunity to escape before it enters the circulator suction, instead of being allowed to go through the hydraulic circuit of the condenser. In designing concrete tunnels, sudden changes in area or sharp corners should be avoided, and overhead beams should not be put in unless in connection with a vent to skim off air.

(*b*) *Tube Losses.* Of the three losses, those through the tubes can be calculated most accurately. They consist of friction, entrance, and exit losses. The friction losses are based on the equation

$$p = \lambda \frac{L}{D} \frac{\rho u^2}{2} \qquad [1]$$

where p = pressure drop, lb per sq ft; λ = friction coefficient, dimensionless; L = length of path of flow which in this study is equal to the tube length, ft; D = inside diameter of tube, ft; u = mean velocity through the tube, or flow by volume divided by the cross-sectional area of the tube, fps; and ρ = mass density of the water, lb sec²/ft⁴. The mass density $\rho = d/g$, where d = weight density of water, lb per cu ft; and g = standard acceleration due to gravity, 32.174 ft per sec per sec.

Customarily the formula

$$h = \lambda \frac{L}{D} \frac{u^2}{2g} \qquad [2]$$

is used, where h = the head loss, ft of water; and the other terms are the same as given previously.

All values, except λ which is a function of the Reynolds number, can be directly calculated for any particular condenser.

According to the latest data of Prandtl-von Kármán (1, 2),[2] for smooth pipe and turbulent flow

$$\frac{1}{\sqrt{\lambda}} = 2 \log_{10}[(\mathrm{Re})\sqrt{\lambda}] - 0.8 \qquad [3]$$

where (Re) = Reynolds' number, and λ = a dimensionless friction coefficient. The form of the formula comes from von Kármán (2) and the constants were determined from tests made by Nikuradse (3) in 1928 and 1929. The formula is also given by Hemke in an American handbook edited by Eshbach (4). This formula is very cumbersome to use, and therefore is given in graphical form in Fig. 1.

The Reynolds number can be calculated from the formula

$$(\mathrm{Re}) = uD/\nu \qquad [4]$$

[1] Consultant, Detroit Edison Company. Mem. A.S.M.E. Mr. Van Hengel was graduated from the Technical University of Delft, The Netherlands, in 1918, with an M.E. degree. After graduation he spent three years in Holland on design and construction of industrial plants. In 1921 he came to the United States for a study trip, and for half a year visited many kinds of factories. He spent six years with the Worthington Pump & Machinery Corporation, Cincinnati, Ohio, and Harrison, N. J., on design, testing, and research of centrifugal pumps, condensers, dry-vacuum pumps, and steam air ejectors. For two and one-half years he was chief engineer of the Issoudun Aircraft Manufacturing Company, Northville, Mich., makers of all-metal amphibians. Since 1930 he has been a consultant for the Detroit Edison Company on steam condensers and auxiliaries.

Contributed by the Power Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

[2] Numbers in parentheses refer to Bibliography at the end of the paper.

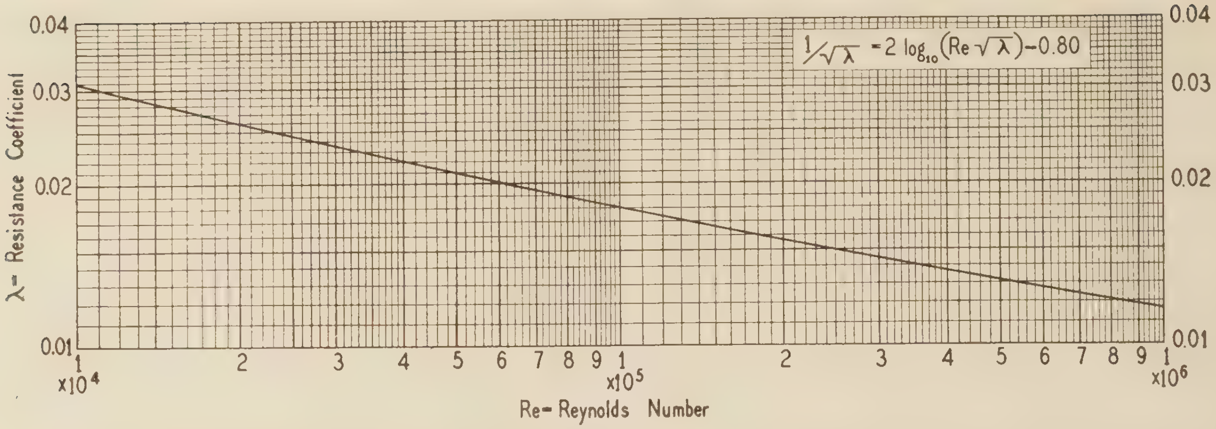

Fig. 1 Resistance Coefficient λ as a Function of the Reynolds Number for Turbulent Flow Through Smooth Pipes
(The formula represents Nikuradse's tests made with water in turbulent flow at Reynolds numbers between 3070 and 3,230,000 through pipes of inside diameters from 0.394 to 3.94 in.)

where ν = the kinematic viscosity of the water ft² per sec. The values of the kinematic viscosity in these units are given graphically in Fig. 2 for water temperatures between 32 F and 212 F. To the author's knowledge, no curve of kinematic viscosity in these units has been published before.

The inlet and outlet losses can easily be expressed as a function of the velocity head $u^2/2g$ as follows: This head loss is $h = C(u^2/2g)$, where C is a constant coefficient depending only on the type of entrance and exit of the tubes. Values for C as found by Guy and Winstanley (5) are 1.5 for tubes ferruled at both ends; 1.25 for tubes bellmouthed and expanded at the inlet and ferruled at the outlet; and 1.00 for tubes bellmouthed at the inlet and expanded at the outlet.

(c) *Condenser-Piping and Water-Box Losses.* The loss of hydraulic head through the condenser piping and water boxes is entirely dependent on the dimensions of a particular condenser unit under consideration. The author will give the calculations for this loss in main unit No. 13 at the Delray Station of the Detroit Edison Company, which was described in a previous paper (6), and then compare them with test results. The 50,000-sq ft single-pass condenser, previously described by the author (6), had a good hydraulic circuit free from unnecessary obstructions. It was designed for a maximum capacity of 120,000 gpm at a total head of 20 ft.

In considering the water flow through irregular shapes and around irregular corners, it is found that the principal losses arise from acceleration and retardation of the water flow, and are not caused by friction. To prove this, assume that the condenser piping and boxes, which in this case have an average area of 30 sq ft, are replaced by a straight pipe line of equivalent area and length. This would be a pipe line of $6^1/_4$ ft diameter with a length of 70 ft along the flow. The friction loss through this straight pipe line would be only 0.1 ft at a flow of 100,000 gpm. This is negligible, as it is not even 1.5 per cent of the 9-ft head loss actually found in the condenser piping and water boxes.

The actual losses are due principally to the sudden changes of direction in the water flow. Assume that we have a 90-deg elbow in a pipe line and that the elbow is a 45-deg miter joint having only one weld. The energy of the water coming from the one direction is of no use to the water going around the sharp corner and the head loss is 110 per cent of the velocity head (7). In a hydraulic circuit of a condenser we have many of these cases. For instance, the horizontal canal velocity at the entrance of the suction pipe of a circulator is virtually of no use for the vertical velocity in the suction pipe.

All the changes of flow in a hydraulic circuit of a single-pass condenser are:

1 Horizontal canal velocity to vertical suction-pipe velocity of circulators.

2 Vertical inlet-water-box velocity to horizontal tube velocity.

3 Horizontal tube velocity to vertical outlet-box velocity at tube-head side of weir (as is the case in Fig. 3 where the weir is parallel with the tube sheet and flat head).

4 Vertical velocity at tube-head side of weir to horizontal velocity over weir.

5 Horizontal weir velocity to vertical velocity in outlet box flat-head side.

6 Vertical velocity in tail pipe to horizontal velocity in canal.

In all these cases a full velocity-head loss, based on mean velocity, can be assumed for the head-loss calculation.

Naturally, other losses can occur, such as those due to contractions of areas; the velocity head calculated from an equal velocity over the area is then too low and the velocity head has to be recalculated from the actual velocity in the contracted area. For a certain flow, the velocity should be calculated from the product of the area present and the contraction factor for the flow.

The largest losses in the hydraulic circuit of a condenser occur at the outlet-box weir. Energy losses due to change of flow as well as to contraction take place at that point. In the overflow of the weir, especially large contraction takes place, and we even find reversals of flow in this part of the condenser (8).

Results and Testing

The static pressures at different points have to be measured in order to test a hydraulic circuit of a condenser. A diagram of the hydraulic circuit of No. 13 condenser at Delray is shown in Fig. 3, with the location of the places where these static pressures were measured. The elevation in feet above the condenser-room floor is noted at each connection for potential head correction, referring all total heads to condenser-room floor. Any other level, however, can be taken. The total head is the static head, plus the potential head, plus the velocity head. No velocity head has to be included for the top of the inlet box or the outlet box and the canal levels, since it is negligible at these points.

In Table 1 are given the results for some summer and winter tests on this condenser and for some tests of the Trenton Channel condensers Nos. 2 and 3. From these tests, the friction coefficients are calculated and shown in Fig. 4. The results from the

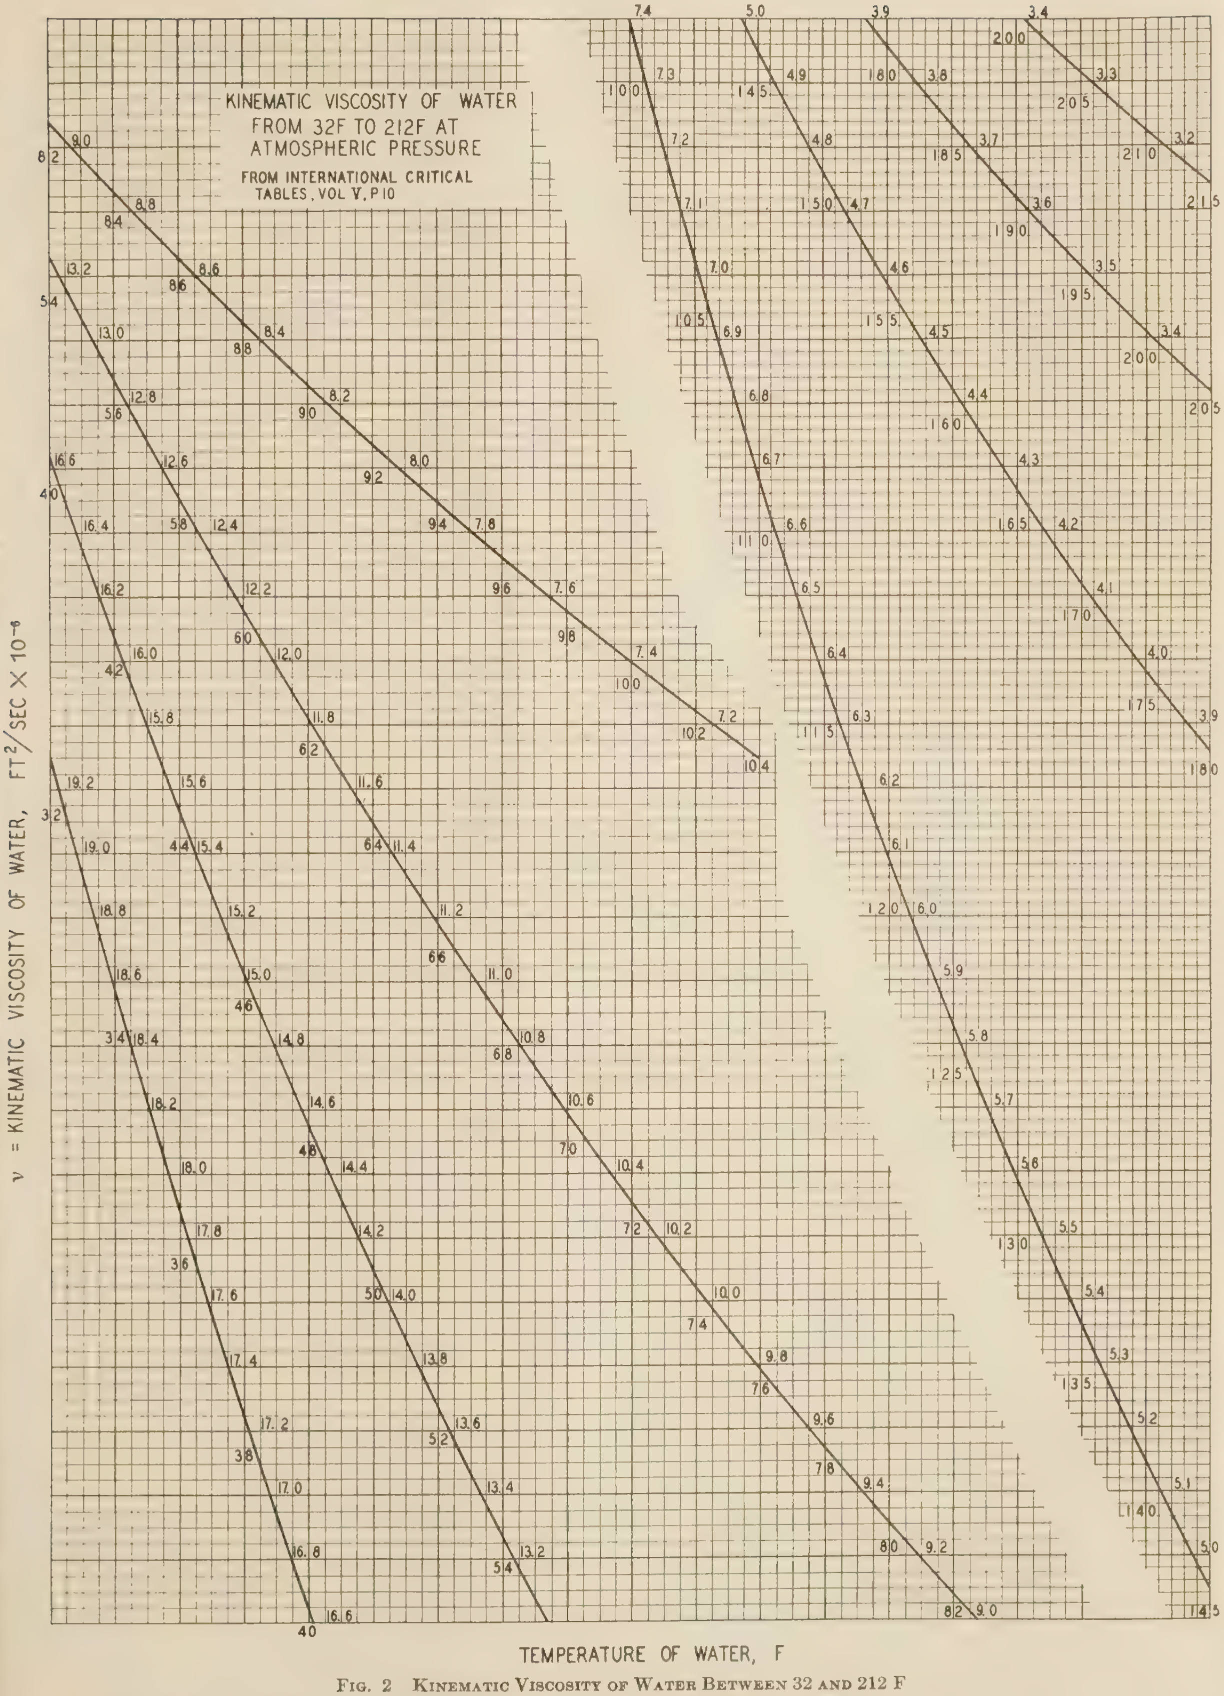

FIG. 2 KINEMATIC VISCOSITY OF WATER BETWEEN 32 AND 212 F

(These values are computed from those of the International Critical Tables, and are applicable to pressures of 1 atm or less.)

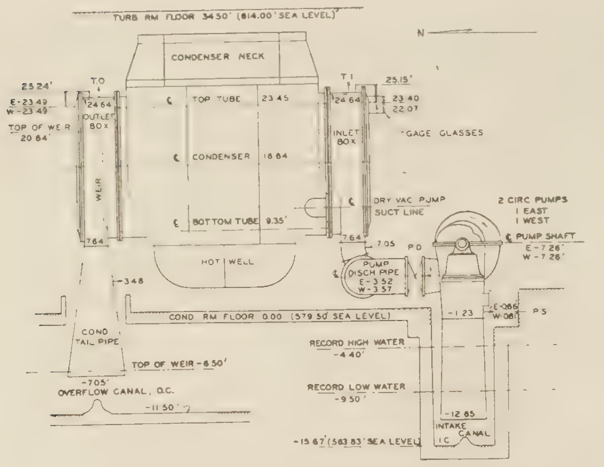

FIG. 3 HYDRAULIC-CIRCUIT ELEVATION OF THE NO. 13 MAIN CONDENSER AT THE DELRAY STATION

(This figure indicates the elevations of the manometer connections, which are marked by crosses, and the elevations of the water-box gage glasses. The locations of the different parts of the circuit are designated by the following letters: Intake canal, I. C.; circulating-pump suction, P. S.; circulating-pump discharge, P. D.; top of inlet water box, T. I.; top of outlet or overflow water box, T. O.; and the overflow canal, O. C. The discharge of each pump has two manometer connections. The outlet water box, divided through its center by a vertical partition into east and west sections, has a manometer connection to each section and a gage glass in each section. For a perspective diagram of this condenser see Fig. 2, p. 629, Trans. A.S.M.E., vol. 58, 1936.)

Delray condenser are somewhat higher, probably because of slight dirtiness of the tubes and also because the friction of the tube cannot be exactly separated from the total losses measured.

Table 2 shows the calculations for 100,000 gpm (two pumps) and 50,000 gpm (single pump) water flow through this condenser. The losses are calculated separately for each point of the circuit where they occur. They are grouped together for each section of the circuit between two successive points of measurement, shown in Fig. 3 and given in Table 1, items 41 to 46 inclusive.

The losses through the tubes are calculated under the heading of "top inlet box–top outlet box" in Table 2. In this loss a part of the weir loss is also included. This loss, with the inlet and outlet losses of the tube, has to be subtracted from the measured results between the top inlet box and the top outlet box to obtain the friction loss through the tube. The friction coefficient λ can then be calculated. Weir losses do not have to be deducted in the case of Trenton Channel condenser No. 3 since it had no weir (9). Fig. 4 shows how remarkably well λ calculated from test data agrees with the theoretical value, especially for the Trenton Channel tests.

A good idea of the change of the losses in the hydraulic circuit with change in water flow can be obtained by plotting a curve, as shown in Fig. 5. This curve also shows the consistency of, and gives a check on, the test results. This can be done for all other drops of the circuit except for top in–top out, where changes of the friction coefficient λ with the Reynolds number are involved.

TABLE 1 SUMMARY OF DATA AND RESULTS OF HYDRAULIC-CIRCUIT TESTS[a]

Item			Delray No. 13 Condenser — Weir in 8143 tubes[b]									
1.	Run No.		65	66	67	68	49	50	51	52	20	22
2.	Date (duration 1-1/2 hour in most cases)		1/7/36	1/7/36	1/7/36	1/7/36	8/13/35	8/13/35	8/13/35	8/13/35	4/4/35	4/4/35

[a] All condensers are single pass.

[b] Tubes in all cases are brass; 1 in. O.D., 0.902 in. I.D., 24 ft long.

[c] Velocities and velocity heads are computed from division of circulating water flow (heat balance) by flow areas.

[d] C.R.F. = condenser room floor; water standing still with a static pressure of 1 atmosphere abs at the condenser room floor level would have a total head of 0.00 ft. Minus signs indicate distance of water levels below condenser room floor; water levels above condenser room floor have plus signs.

[e] 30-inch manometers filled with mercury or acetylene tetrabromide; minus sign indicates vacuum. Fig. 3 shows locations of connections for Delray No. 13, which were 1/4-inch diameter flush holes. Pump suction and discharge static pressures as listed have been corrected to elevation of manometer connections, which are given in the following table for the different condensers, in feet referred to the condenser room floor:

Item	Condenser:	Delray 13	Trenton 2	Trenton 3
	Circulator Manometer Connections

25	EPD	3.52	3.14	3.17
26	WPS	-0.61	-2.72	-2.59
27	WPD	3.57	3.22	3.31
	Circulator Shaft C.L.	7.26	6.81	6.73
	Top of Inside of Water Boxes	24.64	22.18	22.15

The Efficiency of the Hydraulic Circuit

By efficiency is meant the ratio of the useful head spent to the total head spent. The useful head in a condenser is assumed to be the head spent on the friction of the tubes plus inlet and outlet losses of the tubes. The total head spent is the total head on the circulators. In the Delray case, run No. 65 for 2 pumps, full load, this efficiency is low, being (6.35 ft of water)/(21.61 ft of water) = 29.5 per cent when including the sealing-weir losses in the overflow canal. For special reasons, however, the overflow canal was built at a higher level than the inlet canal as shown in Fig. 3, and a loss due to a sealing weir in the overflow canal is included in the total head of the pumps. Without this canal-weir loss of 5.05 ft, the efficiency is 6.35/16.56 = 38.5 per cent. This figure is a little above the average, since the inlet and outlet boxes were designed with no horizontal braces, and every effort was made to have a perfect hydraulic pipe system.

In the Delray condenser, 100 — 38.5 = 61.5 per cent of the total head is spent uselessly. Of this, the largest losses occur at the outlet-box weir. Part of the losses due to this weir are included in the losses from the top outlet box to the overflow canal. In the case for 100,000 gpm (see Table 2), they are 3.10 ft of water. To this, the losses due to the upward flow at the tube-head side of the weir and over the weir have to be added. These were included in the head loss between top inlet box and top outlet box. These last losses are respectively 1.38 and 0.62 ft of water; thus, a total of 5.10 ft of water or 5.10/14.46 = 35 per cent of the total-head loss through the condenser boxes, piping, and tubes (sealing weir in overflow canal and canal losses excluded) was spent on the weir. If expressed as a percentage of all losses outside the tubes (sealing weir and canal losses excluded), this becomes 5.10/9.05 = 57 per cent. The largest gain in the hydraulic circuit can therefore be made by removing the weir from the outlet box.

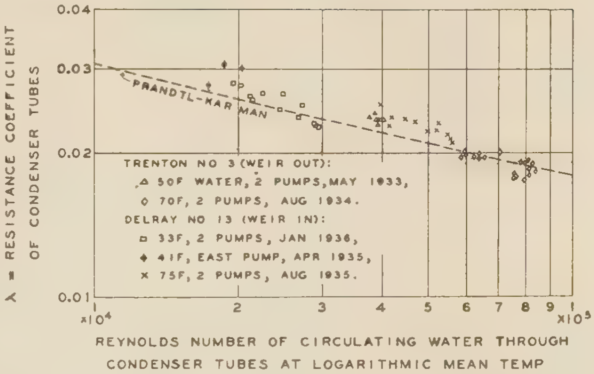

Fig. 4 The Resistance Coefficient λ for Condenser Tubes Versus Reynolds' Numbers of the Circulating Water at the Logarithmic Mean Temperature of the Water

(This figure shows the striking suitability of the Prandtl-von Kármán formulation of Nikuradse's tests of a single tube for condenser-tube banks, which is shown in Fig. 1. The resistance coefficient is for the tube-wall friction only. The Reynolds numbers are calculated from the water velocity through the tubes by the heat-balance value, at the logarithmic mean temperature of the water through the tubes. For the No. 13 condenser at the Delray Station, they are the Reynolds numbers of item 74 in Table 1 of a previous paper by the author (6). Many more test points could have been shown, but those shown are examples of winter and summer test results.)

From each of the existing single-pass condensers Nos. 1, 2, and 3 at the Trenton Channel plant, the author removed an outlet-box weir which was similar to that used on Delray No. 13 condenser, and by doing so increased the efficiency of the circuit from around 28 per cent to around 63 per cent, as shown in Table 1. Part of this high increase in efficiency was due to the additional obstruction in the original design caused by the four butterfly valves in the outlet box (10). This, however, cannot always be done, and will depend on the design of the condenser. A new condenser can be designed without a weir.

The gains involved in the hydraulic circuit by improving its design are therefore worth consideration. For the Trenton Channel and Delray Stations, the average auxiliary power for the circulators is 0.5 per cent of the total generator output under winter conditions, and 1 per cent under summer conditions. For this favorable case of 35 per cent gain in hydraulic-circuit efficiency, a gain of 0.17 to 0.35 per cent of the total generator output is obtained, depending on winter or summer operating conditions.

For a new station, however, it would mean a worthwhile initial reduction in the required installation of auxiliary turbogenerator capacity, as the circulator power runs from 20 to 40 per cent of the total auxiliary power of the station, depending on winter or summer conditions.

Also, in cases where the water quantity is too small, a considerable increase of water can be obtained by taking out the weir; in the case of units Nos. 1, 2, and 3 of the Trenton Channel Station, the increase of water quantity ran around 15 per cent for the same load on the circulators.

The Circulators

Only circulators of high specific[3] speed can be used because of their low head and high capacity. From an operating point of view, the head of the pump at the shutoff point (that is, the point of zero capacity) should be so high at the highest speed

[3] The specific speed N_s of a centrifugal pump on a gallon-per-minute basis is calculated as $(N\sqrt{G})/H^{3/4}$, where N = pump speed, rpm; G = delivery, gpm; and H = total head, ft.

[b] The mixing box at the bottom of the inlet water box is similar to that shown in Figs 117 and 118, p 661, Engineering, June 1, 1928, Vol 125. It has a longitudinal partition so that the water from each pump enters the bottom of the inlet water box across its full width of 12 feet. A symmetry of flow with two-pump operation gives a more favorable turning condition in this mixing box than with one-pump operation. Consequently, a loss of 25% of the velocity head for two-pump operation and of 100% for one-pump operation is assumed.

that the pump can push the water over the weir or highest point of the circuit. In that case, and with a valve in the discharge end of the circulator, the priming of the pump only is necessary to get the water over the weir. If this is not the case, the whole hydraulic circuit has to be primed and this is a handicap to the quick starting of the unit. The priming of the whole circuit takes about 15 minutes against 2 to 3 minutes for a pump alone.

The shut-off point of the circulator will always be high enough to put the water through the circuit if the weir is omitted. When a submerged type of screw pump is used with no weir, all priming lines can be omitted and only vent lines are installed, simplifying the circuit and saving time in starting up.

The Air in the Hydraulic Circuit

Although the siphonic losses have been overestimated, they cannot be ignored in an accurate study of the hydraulic circuit, especially when the siphon is high. A short-cut calculation has been given by Guy and Winstanley (11).

A more accurate calculation will be given. First the amount of air liberated is calculated and then the new density of the water due to volume changes of the air will be calculated.

Air-Water Weight Ratio. River water is always 100 per cent saturated with air, although the ratio of oxygen to nitrogen in the water is somewhat larger than that in the atmospheric air. This difference, however, can be neglected in this calculation. With the use of Henry's law and of the data of Professor Winkler for air dissolved in water under a total pressure of one atmosphere, it is possible to calculate for any condition the volume of the air-water mixture per pound of dry air in the mixture in the circuit. From Henry's law it is known that the amount of a gas dissolved in a liquid is proportional to the partial pressure of that gas on the liquid. Fig. 6 has been calculated from Winkler's 1901 data (12). The weight of air lib-

[c]The water flow through this area is from only 7114 tubes, which are located below top of weir.
[d]100% because of the abrupt change in water box section at weir top and at bottom of overflow box.
[e]30% as a diffusor loss of tail pipe.

erated from a pound of water can be obtained from the difference of two ordinates in Fig. 6. For instance, assume the inlet-water temperature to be 40 F, with a barometer of 30 in. Hg, and the outlet-water temperature at the top of the outlet box to be 60 F and at 10 in. Hg abs total static pressure; then the air liberated is found by subtracting 8.5×10^{-6} lb of air per lb of water in the overflow top from 33.8×10^{-6} lb of air per lb of water as present in the original condition, or 25.3×10^{-6} lb of air are liberated per lb of water.

Volume of Liberated Air. When the amount of air liberated is known, its volume can be calculated with the aid of Dalton's law. This has been done in Fig. 7, which directly shows the volume occupied by the air-vapor mixture for every pound of dry air in the mixture. For the example of 10 in. Hg abs pressure and 60 F, this is 41.2 cu ft per lb of dry air. Therefore, the liberated air per pound of water occupies a space $25.3 \times 10^{-6} \times 41.2 = 1.043 \times 10^{-3}$ cu ft.

Change of Water Density Due to Air. Assuming the weight of 1 cu ft of water as 62.43 lb, then the volume of the air liberated in 1 cu ft of water is $1.043 \times 10^{-3} \times 62.43 = 0.0655$ cu ft. In other words, the density of the water containing 100 per cent air has changed from 62.43 lb per cu ft to $62.43/(1 + 0.0655) = 58.55$ lb per cu ft, a change of 6.3 per cent in weight density. With these figures, the new density can be easily calculated for

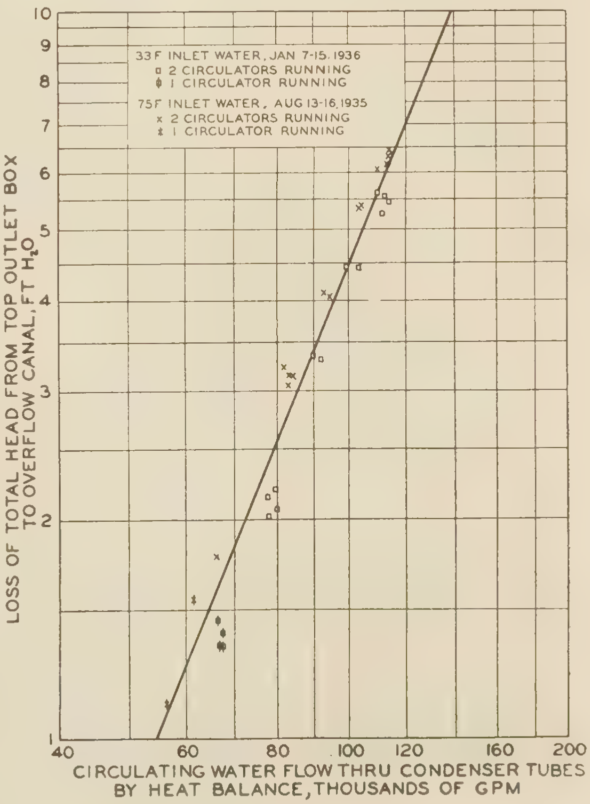

FIG. 5 (RIGHT) LOSS OF TOTAL HEAD FROM TOP OUTLET BOX TO OVERFLOW CANAL VERSUS CIRCULATING-WATER FLOW THROUGH CONDENSER TUBES BY HEAT BALANCE FOR THE NO. 13 CONDENSER AT THE DELRAY STATION

(This total-head loss is item 46 of Table 1, which is the difference between item 40A and item 32 of that table, and allows for the entrained air in the outlet-box water column. The circulating-water flow is item 11 of Table 1. The figure illustrates the straight-line relationship obtained on logarithmic paper for losses between points; the slope of the line is approximately 2.)

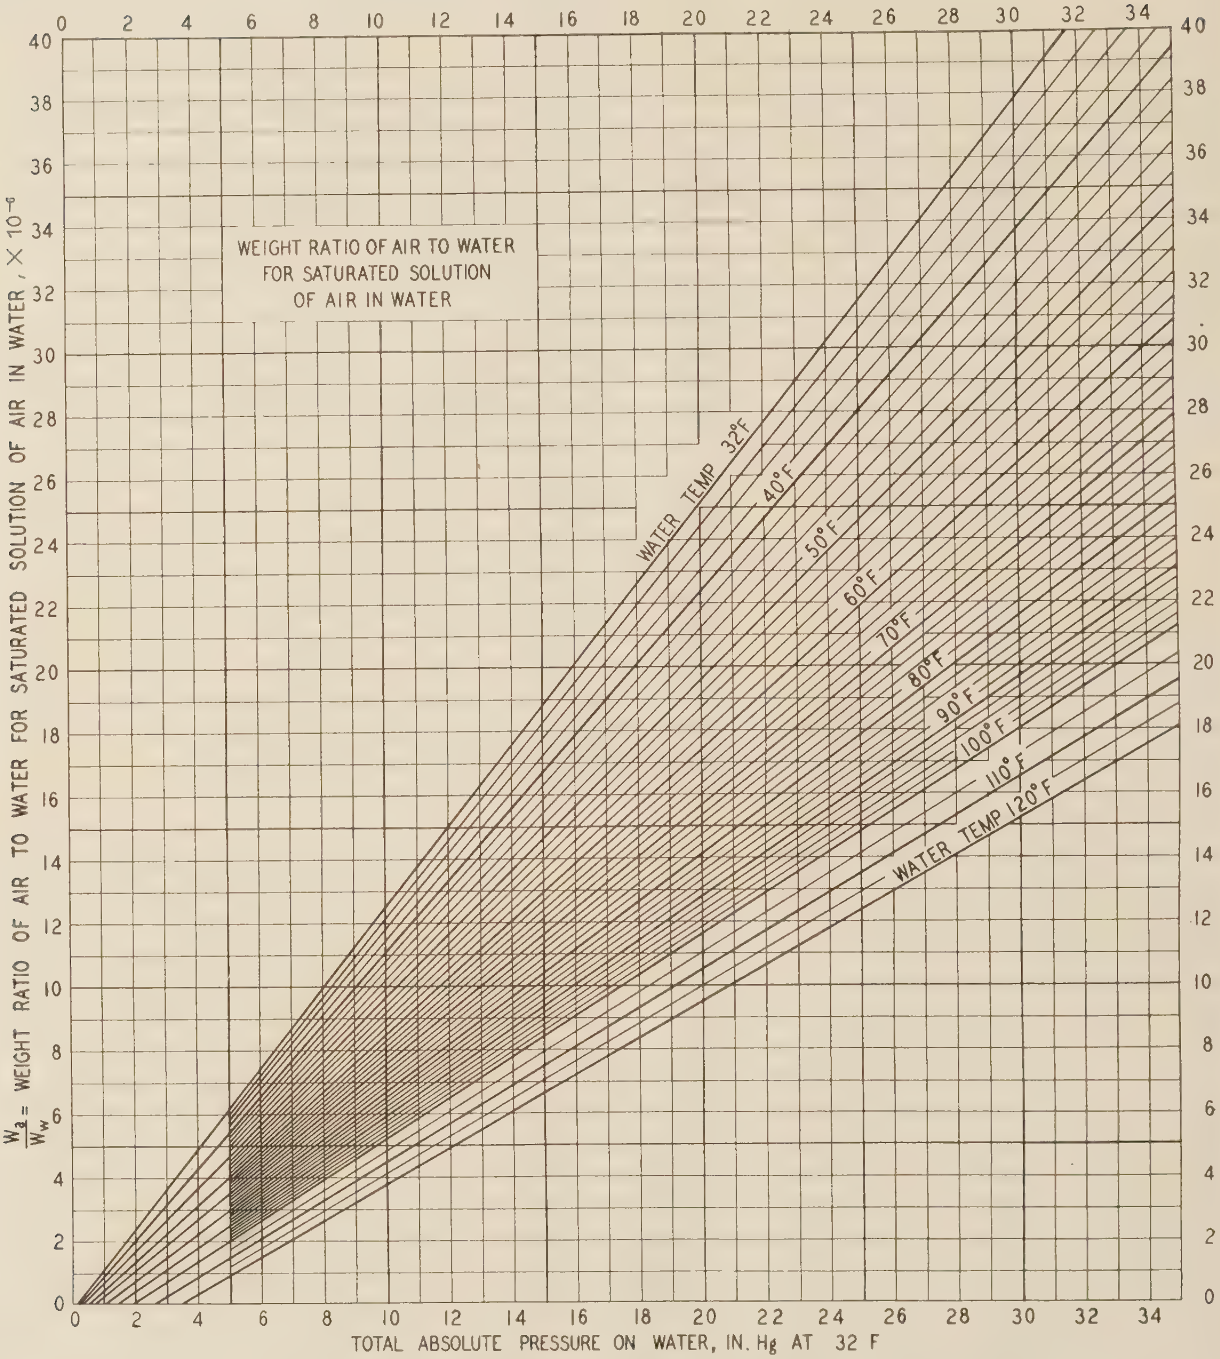

FIG. 6 WEIGHT RATIO OF AIR TO WATER FOR A SATURATED SOLUTION OF AIR IN WATER

(Lines of different water temperature from 32 to 120 F are plotted for total pressures on the water from 0 to 35 in. Hg abs, the total pressure being the sum of the partial pressure of the water vapor and the dry air over that water. The lines are straight because, according to Henry's law, the weight ratio of dissolved air to water is linearly proportional to the partial pressure of the dry air in the mixture of air and water vapor over the water. These data are calculated from the International Critical Tables (12) where is given for different temperatures, the total dry-air content V_d in 1000 cc of water 100 per cent saturated with air at a total pressure of 760 mm Hg; the dissolved-air content is measured in cubic centimeters referred to standard conditions of 0 C and 760 mm Hg. The weight ratio of dissolved air to water is computed as

$$\frac{W_a}{W_w} = \frac{p_a \text{ at } p_t}{p_a \text{ at 29.921 in. Hg}} \times \frac{d_a \text{ at 29.921 in. Hg and 32 F}}{d_w} \times \frac{V_d}{1000}$$

where W_a = weight of dissolved dry air in solution with water 100 per cent saturated with air; W_w = weight of water containing W_a weight of air; p_a at p_t = partial air pressure at total pressure p_t and at the temperature for which V_d is given, in. Hg at 32 F; $p_a = p_t - p_s$; p_s = saturation pressure of steam at the temperature for which V_d is given, in. Hg at 32 F; p_a at 29.921 in. Hg = partial air pressure at 29.921 in. Hg total pressure and the temperature for which V_d is given, in. Hg at 32 F; d_a = standard weight density of air, 1.2929×10^{-3} g per cc, International Critical Tables, vol. 3, p. 3, or 0.080714 lb per cu ft; and d_w = weight density of water at the temperature for which V_d is given, g per cc. Density d_w can be obtained from the International Critical Tables, vol. 3, 1928, p. 25. The graph is based on an identical molecular weight of 28.958 for both dissolved and free air. Actually, dissolved air contains about 13 per cent more oxygen than free air. The composition of air dissolved in 32 F water corresponds to a standard weight of 0.08231 lb per cu ft, and for air dissolved in 86 F water, 0.08212 lb per cu ft.)

any point in the circuit, when the static pressure is known. One problem which is still left is the change in weight density due to the static-pressure changes that occur with change in height of level, because the potential pressure changes. An integration over a certain height of water column is therefore necessary for the different densities. This has been worked out as curves in Fig. 8, which gives the correction for the height of a standing column under different absolute pressures at the top of the column and at different temperatures of the column. The tests (see Table 1) give the level difference between the top of the outlet box and overflow canal. But, at the level of the overflow canal, the water inside the tail pipe still has free air present because it was saturated at inlet temperature and not at outlet temperature. A higher pressure is necessary to redissolve all air at the higher temperature. Fig. 6 gives the pressure at

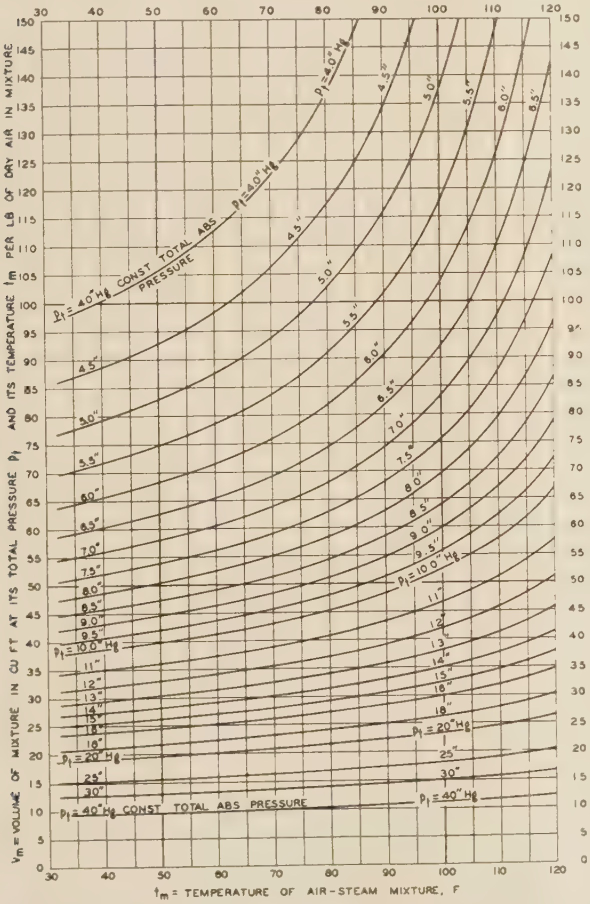

Fig. 7 Volume of Air-Steam Mixture, of 100 Per Cent Relative Humidity, Per Pound of Dry Air at Different Temperatures and Total Pressures of Mixture

(This graph represents the equation $(p_t - p_s)V_m = 0.7541(t_m + 459.6)$ where p_t = total absolute pressure of the mixture, in. Hg at 32 F; t_m = temperature of mixture, deg F; p_s = steam saturation pressure at t_m, in. Hg at 32 F; and V_m = cu ft of mixture per lb of dry air.)

which all the air will dissolve at the higher temperature when moving along a constant ordinate from the lower pressure to the higher pressure, since both conditions have to have the same weight ratio of dissolved air to water. This additional pressure added as feet to the level difference between the top of the outlet box and the overflow canal level gives the total height to be corrected. Fig. 8 gives the correction to be applied for water from 32 to 90 F, and for 30 in. Hg total pressure, and an additional

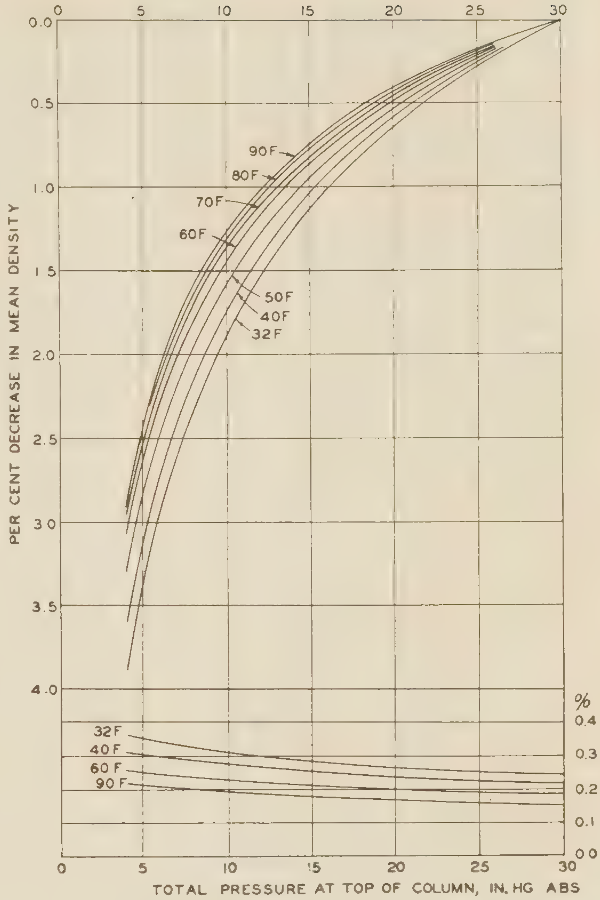

Fig. 8 Correction to Mean Density of Vertical Water Column for Decrease Due to Liberated Air

(The data of the figure have been computed for a standing column, but they apply as well to a column of moving water, providing the change of static pressure from bottom to top is approximately linear. The curves in the upper part of the figure apply to water which is saturated with dissolved air at the regular atmospheric condition which is assumed to be a total pressure of 30 in. Hg. This curve is to be used for the inlet water box where no changes of temperature have taken place as yet. The curves in the lower part of the figure show the minor additional decrease of mean density (at the right of the figure) if the pressure at saturation is 35 in. Hg instead of 30 in. Hg. This has to be applied for the overflow where the temperature rise has raised the saturation pressure.)

correction to be applied in case a total pressure of 35 in. Hg is necessary to redissolve all the air. For total pressures between 30 and 35 in. Hg, a prorata correction has to be applied. Sample calculations for four of the runs are included in Table 3.

It is mentioned here that the siphon losses due to air in the circuit have been overestimated, and that they amount to only 0.5 ft for a 26-ft siphon in case the vent line from inlet to outlet box takes care of the free air.

The downward velocity in the outlet box and tail pipe should always be kept above 1.5 fps so that no liberated air can rise against the flow of water (13, 14). For calculation of thoroughly safe conditions, so that possible air leaks in the hydraulic circuits can be taken care of, it is better to use a value of 2 to 3 fps. (See Table 2, Item 11, column 5 or g.)

Fig. 9, based on data obtained on unit No. 13 at the Delray Station, gives a picture of the flow velocity in the overflow below the joint between the bottom of the outlet box and the top of the tail pipe. The values were obtained from a pitot-tube traverse. Although the velocity at the center dropped considerably, due to the vertical brace in the outlet box, it is clearly noticeable that

in each half of the pipe the highest velocities occur toward the center of the pipe as a whole. This is a result of the flow condition over the top of the weir, where the largest flow occurs toward the center line of the outlet box. At this point the flow area above the weir is a segment of a circle of which the weir top forms the chord.

Venting of Condensers. More attention should be given to the venting of inlet boxes, return boxes, and centrifugal-pump discharges, especially if salt water is used as a cooling medium.

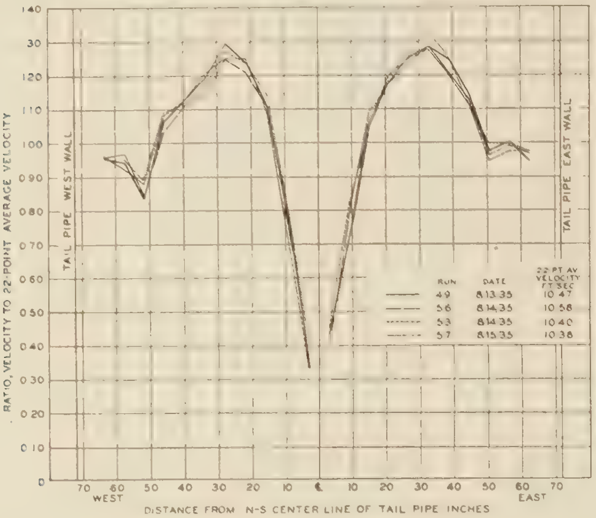

FIG. 9 VELOCITY DISTRIBUTION OF OVERFLOW CIRCULATING WATER ALONG THE LONG CENTER LINE OF THE 30 × 144-IN. TAIL-PIPE TOP FOR NO. 13 CONDENSER AT DELRAY STATION

(These curves, which are for four runs with 75 F inlet circulating water, and with both circulators operating at their highest speed of 240 rpm, are typical of many other runs with both circulators running at equal speeds over the whole speed range of 180 to 240 rpm, and with inlet circulating-water temperatures varying from 40 to 75 F. The traverse was made in the top of the tail pipe close to the location of the outlet thermocouples, or at an elevation of 6.39 ft above the condenser-room floor. It was made with two Cole pitometers, which were adjusted to 22 station points approximately 3 in. apart. The mid-point of each half of the pipe was checked before and after each traverse. Pitometer pressures were measured with 30-in. manometers filled with acetylene tetrabromide. Location of the pitometers is shown in Fig. 2 of a previous paper by the author (6). The decrease in velocity at the center of the pipe is caused by the vertical brace in the center of the outlet box. The traverse was made only 2.5 ft below foot of that brace, which is 10 in. wide and 30 in. long. The tail pipe was braced with five 1/2 × 30-in. braces.)

Bad venting of inlet water boxes will cause the air to flow through the tubes and cause corrosion at the inlet end of the tube, because of the contraction of flow which takes place. Also the heat transfer suffers, especially for the top tubes which will act as vent lines in case the installed vent is not of sufficient capacity.

In general, the vent lines applied are all too small, and have insufficient capacity for handling the volume of rarified air that is liberated. The small amount of pressure drop available from the top inlet to outlet box cannot handle this quantity. For a 50,000-sq ft condenser, a 3 to 4-in. vent line is necessary to handle the air satisfactorily instead of the usual 1 1/2 to 2-in. line.

The worst condition occurs at the lowest circulator speed or smallest circulating water flow through the condenser. Assume that the mean pressure of the water in the inlet box is at its center line; then, the volume of the air liberated from 75,000 gpm of water will be around 6 cfs referred to the pressure at the top of the water box (15). In a 2-in. line, this would give a velocity of 260 fps or 15,600 fpm. Under this condition, a pressure drop of 5.4 in. Hg is available between the inlet and outlet boxes, which is only half the pressure difference necessary to transport this volume of air through a 2-in. vent line.

This problem of air is a serious one. Its existence can be quickly proved by taking a vertical traverse in a horizontal discharge line of one of the pumps to a condenser. Such a test showed that at the top of a 48-in. discharge line of a circulator, a space 2 in. high was occupied by air. The worst condition, such as this one was, will happen when the discharge pressure of the circulator is below atmospheric pressure. Free air from the outside atmosphere is often taken in directly through the suction pipe of the circulator. A hollow swirl which is caused by the prerotation of the circulating water in the suction pipe and which extends into the intake canal will bring this free air directly into the system. In case this happens at the design operation of the pump, its impeller should be redesigned.

A good liberation of the air in the inlet box should be provided for. This can be secured by boxes which allow low water velocities and which are free of obstructions. Consequently, the boxes should be wide and have no horizontal braces.

CONCLUSION

The losses of a hydraulic circuit can be calculated within an accuracy of 10 per cent. The weir in single-pass condensers, and not the siphon, causes the highest losses and should be eliminated whenever possible. Abrupt changes in direction of flow should be eliminated. The entrance losses due to bellmouthed or ferruled tubes are overestimated. The liberated air in the water can be determined under all conditions and should be taken care of by adequate venting, because of the possibility of corrosion under salt-water conditions.

ACKNOWLEDGMENT

The author wishes to acknowledge the opportunity given him by The Detroit Edison Company to obtain and publish these results.

Formulas for Stresses in Bolted Flanged Connections

By E. O. WATERS,[1] NEW HAVEN, CONN., D. B. WESSTROM,[2] HARTFORD, CONN., D. B. ROSSHEIM,[3] AND F. S. G. WILLIAMS,[4] NEW YORK, N. Y.

Progress in pressure-vessel design and fabrication during the past two decades has brought about a marked change in the form of bolted connections. Whereas flanges were formerly provided with hubs of approximately uniform thickness, screwed to or slipped over the shell or pipe, it is now customary to use tapered hubs, and an integral structure is obtained by butt welding the end of the hub to the shell. This has invalidated former methods of design for flanged connections.

This paper outlines a revised analysis based on the ring, tapered hub, and shell being considered as three elastically coupled units loaded by a bolting moment, a hydrostatic pressure, or a combination of the two. Design formulas and charts are given for the computation of stresses that are likely to be critical, and their application is illustrated by three problems taken from current commercial practice.

Introduction

FOR THE last two decades there has been a steady increase in the pressures and temperatures employed in the generation of steam and in the process industries. This development has been coincident with a rapid increase in the size of the units. Approximate methods of design that had previously been acceptable could not be used for high-temperature high-pressure designs involving large equipment. With high temperatures and pressures, encroachment on safe operation could not be tolerated; and at the same time, the size of most units demanded economy in design without any compromise with safety. The result has been a steadily increasing need for flange-stress formulas which are correct over a wide range.

During this period, methods of construction have also undergone radical changes. Earlier flange designs were nearly all based on flanges having hubs of approximately uniform thickness. The advent of welding has changed this and the most commonly used construction involves a flange with a tapered hub which is butt-welded to a shell or pipe.

A number of different methods have been used for calculating the stress in a flange, which are reviewed later in this paper. The general observation can be made, however, that in each case they had limitations which confined their use to certain types or ranges of flange cross section.

Extensive interest in the subject dates back to about 1927 when the Taylor-Waters formulas were presented before the A.S.M.E. (1).[5] These formulas had been based upon, and checked by, actual deflection tests conducted by J. Hall Taylor in 1924 and 1925. This method of calculating the stress in a flange has been the one most widely used since that time for the reason that it was substantiated by test data and was reasonably accurate over a wide range.

Flange design became a subject of extensive discussion and the methods of approaching and handling the problem of practical design were numerous. This resulted in the appointment of a joint committee composed of representatives of the A.S.M.E. Boiler Code Committee, the Joint A.P.I.-A.S.M.E. Pressure Vessel Committee and American Standards Association Committee B16E. In 1934 this committee drafted a set of rules (2) which set up a uniform procedure covering all important phases of the design, and represented the first known effort to introduce a rational stress analysis into the commerical design of flanged connections. This committee is continuing its work in an effort to improve these rules and recently it has had the additional assistance of the Heat Exchanger Institute.

One of the most important actions of this committee was a recognition of the importance of the longitudinal bending stress in the hub. Prior to the publication of these rules most designs had simply checked the tangential stress at the inner diameter of the flange and had ignored the possibility of the hub stress being the critical factor. The formula for the hub stress appeared in the Taylor-Waters paper (1) of 1927 but was not generally used.

Because of the conditions mentioned, the authors wish to present in this paper a condensed discussion of the problem of flange

---

[1] Associate Professor of Mechanical Engineering, Yale School of Engineering, Yale University. Mem. A.S.M.E. Professor Waters has been engaged since 1914 in the teaching of engineering subjects in the field of machine design and applied mechanics, with the exception of one year in the Ordnance Department, U.S.A., where he served under the Chief Ordnance Officer, A.E.F., in maintenance and construction work. For the past 10 years he has been a consultant on various problems of stress analysis in connection with the design of pressure vessels.

[2] Home Office Engineer, The Travelers Indemnity Company. Jun. A.S.M.E. After receiving an M.E. degree from Stevens Institute of Technology in 1927, Mr. Wesstrom spent five years with the M. W. Kellogg Company in research in the design of pressure equipment. In 1933 he entered the services of the Lummus Company as a designer and inspector. Since 1935 he has been employed in the engineering and inspection division of the Travelers Indemnity Company. He is active on several committees of the A.S.M.E., is chairman of the Boiler Code Subcommittee on Special Design, and is chairman of the A.S.M.E. Special Committee on Rules for Bolted Flanged Connections.

[3] Mechanical Engineer, M. W. Kellogg Company. Mem. A.S.M.E. Mr. Rossheim attended the University of South Carolina as an undergraduate in civil engineering, and later entered the United States Naval Academy. He was graduated in 1920 as an Ensign in the United States Navy, from which grade he resigned in 1923. After serving in the employ of several manufacturers of boilers and tanks, he became a member of the engineering staff of the M. W. Kellogg Company in 1927. He is a member of the A.S.M.E. Boiler Code Subcommittee on Special Design and other engineering committees.

[4] District Manager, Taylor Forge & Pipe Works. Mem. A.S.M.E. Mr. Williams was graduated with a B.S. degree from Yale University in 1925, and since that time has been connected with the Taylor Forge & Pipe Works. He is a member of the A.S.M.E. Boiler Code Subcommittee on Special Design, and also a member of several other engineering committees on pressure-vessel design.

[5] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Power Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

stresses and their calculation. The various methods that have been used are summarized with a brief analysis of each, and finally formulas are presented that are believed to give accurate results over a wide range.

Review of Earlier Work

Brief comments on some of the more important developments in the calculation of flange stresses will serve as a background for this paper.

Perhaps the earliest method of calculation to receive wide attention was the so-called "*Locomotive*" method, (3) generally credited to the late Dr. A. D. Risteen. The section *abcdefg* in Fig. 1 is assumed to rotate counterclockwise, but without distortion. The final equation is in effect the conventional flexure formula, the external moment being the total bolt moment per radian angle and the section modulus being that taken about the axis X-X' through the center of gravity O. For ring flanges this gives the tangential stress on either face, and for hubbed flanges it gives the tangential stress at the free end of the hub.

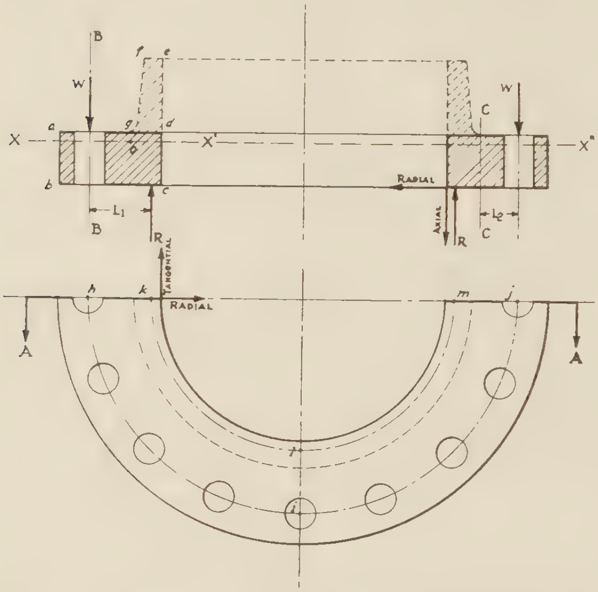

Fig. 1 Illustrations of Earlier Methods of Calculating Stress in a Bolted Flange

Crocker and Sanford developed a method (1, 4) whereby the flange is analyzed as a beam, in which bending about the neutral axis X-X'' takes place on the section A-A, and the external loads are one half the bolt load W and one half the reaction R, each concentrated at the center of gravity of their respective half-circles *hij* and *klm*. (The location of the bolt-load circle, however, was assumed tangent to the inner edge of the bolt holes, and not along the bolt circle as shown in Fig. 1.) This method likewise gives the tangential stress on either face of a ring, or at the free end of the hub.

Den Hartog (4) showed by vector analysis that although the *Locomotive* and Crocker-Sanford methods are derived in different ways, they are fundamentally identical.

A method devised by Tanner for ring flanges, and discussed by Waters and Taylor (1), is to assume the ring to be fixed at the section B-B around the bolt circle and to be equivalent to a cantilever beam of length L_1 with the "concentrated" load R uniformly distributed across a width equal to the circumference of the ring. This method gives the radial stress assumed to be present at section B-B. In the application of the method, Tanner took account of the tangential stresses by using suitable factors derived from experiments on rings of the proportions in which he was interested. The Tanner method was modified by Crocker (1, 4) for application to hubbed flanges (and presumably adaptable to ring flanges also) by assuming the fixed section to be the weakest section C-C in the ring at the base of the hub, with the load W "concentrated" at the distance L_2 at the free end and distributed along the bolt-loading circle. This likewise results in a calculation of the radial stress assumed to exist, in this case at section C-C.

None of the foregoing methods took into account all the conditions present in the flange under load, and so the Waters and Taylor paper in 1927 (1) based on a combination of the flat plate and the elastically supported beam theories, was probably the first instance in which the stress conditions in a flange in the three principal directions—tangential, radial, and axial—were explored with the object of determining the location and magnitude of the maximum stress. Formulas were included for the deflection of the ring, and the calculated deflections were compared with those actually obtained in several series of tests, the data of which were also reported. Because in flange proportions considered at that time the tangential stress in the ring at the inside diameter was the controlling factor, the formulas for stresses elsewhere in the flange were generally overlooked by designers.

The Waters-Taylor paper evoked extensive discussion (4) in the course of which Timoshenko presented an analysis for both ring flanges and hubbed flanges, including a method of dealing with hubs shorter than the so-called "critical" length. Most of these formulas can be found also in his work on "Strength of Materials" (5).

In 1931 Holmberg and Axelson wrote a paper (6) in which they used the flat-plate theory in developing formulas for stresses in loose-ring flanges and in flanges made integral with the wall of a pressure vessel or pipe.

In a series of articles recently published (7), Jasper, Gregersen, and Zoellner discussed further the formulas of Timoshenko, and Holmberg and Axelson. They also made an outstanding contribution to the subject by presenting the results of an extensive series of tests on plaster-of-paris models. Some of the data obtained were used in developing an analysis of the stresses in hubbed flanges having a large circular fillet at the junction of hub and ring.

When the rules for flanges in the A.S.M.E. and the A.P.I.-A.S.M.E. Unfired Pressure Vessel Codes (2) were first published in 1934, the wide range of their application made it necessary to use formulas based on a rational and complete theory, and because the Waters-Taylor equations met this requirement and had been checked by experiment, they were adopted, with auxiliary charts to simplify the calculations. The radial-stress formula was omitted, however, because it was not believed that it would be the critical factor in any practical design.

Several years of experience with the A.S.M.E. rules and the rapid development of large-size equipment for high pressures and temperatures have indicated the need for a revamping of these formulas. The influence of shearing forces at the junction of hub and ring was not included in their derivation, and this effect is important in many instances. The formulas are inconvenient to handle because they are based on the mean diameter and thickness of the hub; also, other assumptions on which they are based lead to difficulties. The method of handling hubs of nonuniform thickness, such as tapered hubs and large circular fillets, has proved unsatisfactory and it is believed does not give proper credit for reinforcement provided by such designs, where

a small amount of metal is so distributed as to result in greatly increased strength.

In the sections that follow the authors develop a method of flange-stress calculation, which it is believed will be easier to handle than the previous form of the formulas, and which is accurate over the complete range of practical design covering hubs of either uniform or tapered section.

Basis of the Present Study

The formulas presented in this paper can be applied to the circular flanges of bolted joints under pressure, such as flanges on heat exchangers, condensers, vulcanizers, and piping, when the flanges are free to deflect under the action of the bolt pull. This includes all types of flange facing where the gasket or contacting flange surfaces are entirely within the bolt circle, and excludes all cases where there is any contact outside of the bolt circle, as in a full-face gasket.

It is assumed that the flange is made of a homogeneous material having stable elastic properties and that these properties obtain under the conditions of loading assumed in the design. It is beyond the scope of this paper to discuss what occurs when the material becomes plastic. However, the general statement may be offered that when using these formulas to design steel flanges for high-temperature service, creep or progressive plastic deformation need not be taken into account if the design is such that the calculated stresses do not exceed the values at which creep will have an appreciable effect. In other words, the design should be based on the conditions obtaining in service after relaxation of the bolts and flanges is practically complete, using an appropriate safety factor.

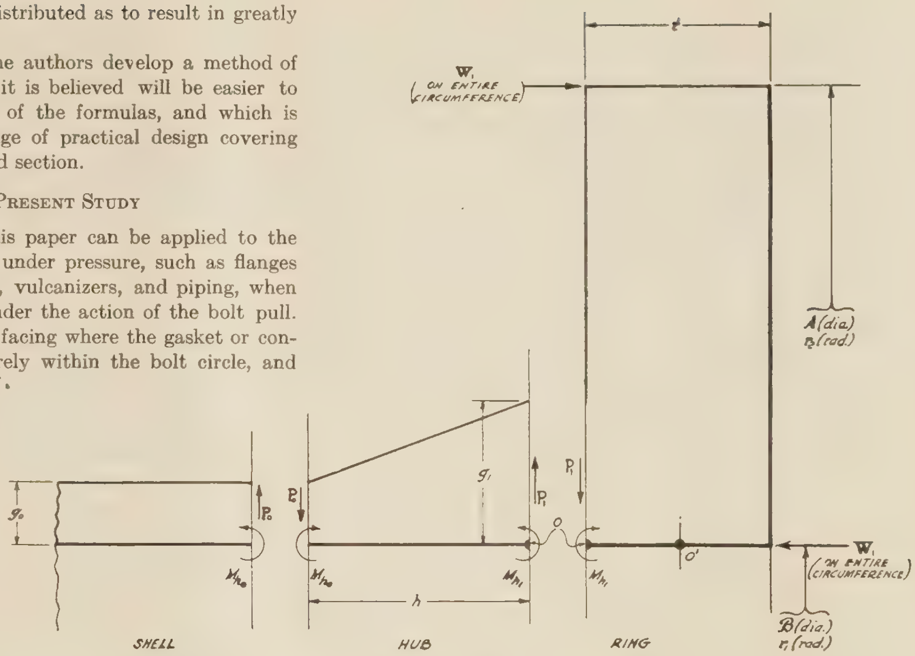

FIG. 3 ANALYSIS OF FORCES AND MOMENTS IN A TAPERED-HUB FLANGE

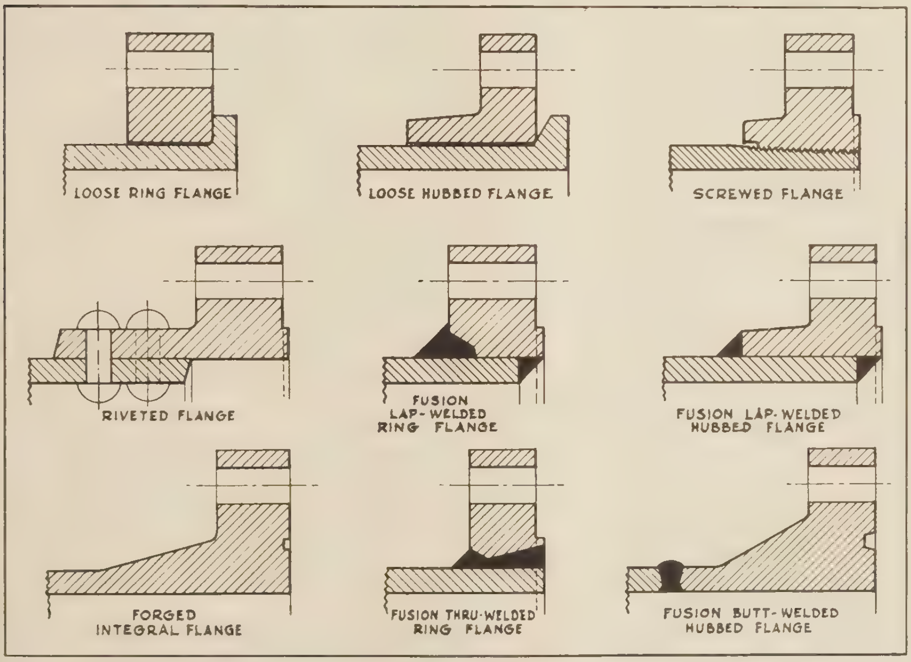

FIG. 2 SOME TYPES OF FLANGES TO WHICH THE AUTHORS' FORMULAS ARE APPLICABLE

It is not the purpose in this paper to deal with the probable stresses set up in the bolts on tightening them, or with the gasket or contact pressure required either to seal the contact surfaces or to maintain pressure tightness. These are separate items in the general subject of flange design and can be considered independently of the study of stresses in the flange under any given bolt load. It is assumed therefore that the bolt load has been determined, and this is used as a starting point.

It is also assumed that the lever arm of the bolt load has been determined. Most flange designs involve a compound lever arm, and a method, not theoretically exact but sufficiently approximate for practical purposes, for calculating compound lever arms may be found in Par. UA-20 of the A.S.M.E. Unfired Pressure Vessel Code or Par. W-317 of the Joint A.P.I.-A.S.M.E. Unfired Pressure Vessel Code (2).

The further assumption is made that for practical purposes the effect of the external moment on the flange, equal to the product of the bolt load and the lever arm, is the same in all cases, regardless of the location of the bolt circle and of the forces balancing the bolt load. This assumption may appear rash, but studies have been made that indicate it is practically true for ring flanges without hubs, and it is reasonable to suppose that

the same would obtain for hubbed flanges. The equations in the paper by Holmberg and Axelson (6) enable a study of the effect of applying the external loads at various diameters of a ring flange, and a detailed analysis of these equations has shown that the points of application can be varied over wide limits without affecting the results to any practical extent.

It should be noted here that the formulas presented herein are applicable to flanges without limit as to diameter, pressure, and temperature, and aside from the restriction as to type of flange facing noted previously, to flanges of all types. Some of these types are illustrated in Fig. 2, in which obviously the various forms of flange facing may be interchanged. Thus the formulas may be applied to loose flanges, with or without hubs, screwed flanges and flanges attached by riveted or welded lap joints, and integral flanges and flanges made integral by through welding a ring or butt welding a hub. In the Unfired Pressure Vessel Code (2) screwed flanges are considered as loose flanges because the shell or pipe offers very little, if any, resistance to the deflection of the flange. Flanges riveted and welded by means of lap joints are also considered as loose flanges. This results in a heavier flange, which is desirable in order to keep the unknown tension stresses on the rivets and fillet welds at a reasonable minimum.

The following analysis considers the general case of a tapered-hub flange, in the course of which a loose-ring flange, a loose flange with hub, and either a loose or integral flange with hub of uniform thickness are shown to be special cases of the general one.

Analysis of Stress Distribution

The tapered-hub flange may be subdivided into three portions, which will hereafter be termed the ring, hub, and shell, as shown in Fig. 3. Each portion may then be studied as an independent unit, with undetermined boundary conditions (displacement, rotation, moment, shear) at the junction surfaces. When the portions are assembled, each of these boundary conditions on one side of any junction surface is identically equal to a corresponding condition on the opposite side; in addition, certain conditions are known at the free boundaries of the assembled flange. Hence, sufficient relations exist for the evaluation of all boundary conditions in terms of the external loading, the dimensions of the flange, and the elastic constants of the material. From the mathematical standpoint, the problem is then completely solved; practically, it remains to investigate certain stress distributions and, if possible, establish simplified formulas, so that the labor of checking critical conditions in existing designs, or determining the proportions of new designs, may be lightened as much as possible.

The analysis may be greatly simplified by making the following assumptions:

1 Due to axial symmetry, the complete flange may be replaced by a unit sector, i.e., a sector whose plane faces have the form of Fig. 3 assembled, and include an angle of $1/r_1$.

2 The loading consists of (*a*) internal hydrostatic pressure acting radially on the bore of the flange and, through an assumed closure, in an axial direction as well; and (*b*) a moment acting on the ring, so distributed that it may be replaced by an equivalent couple applied at the inside and outside diameter of the ring.

3 Stretching of the middle surface of the ring, due to application of the ring moment, is negligible.

4 Dishing, or rotation, of the ring is small, so that the two load systems and their elastic effects are linearly related; and the complete problem may be solved by superposition.

5 When the ring moment is the only external load in action, point O shown in Fig. 3 has negligible displacement.

6 The hub and shell may be treated as membranes subject to tension and bending, and the radius to the middle surface may in general be used interchangeably with the inside radius r_1 shown in Fig. 3.

The following nomenclature is used throughout; in addition, the design formulas employ a notation, explained later, wherein the effort has been made to retain correspondence with present Boiler Code usage, as far as possible. In Fig. 3, where many of these symbols are indicated, it should be noted that forces and moments are shown in the direction which is taken as positive in this paper.

Nomenclature

A = outside diameter of ring, in.
a = lever arm, which when multiplied by the total bolt load W gives the total moment loading on the ring, in.
B = inside diameter of ring, hub, and shell, in.
c_n = constant of integration
D = flexural modulus of ring $= \dfrac{Et^3}{12(1-\nu^2)}$, in-lb
E = Young's modulus, lb per sq in.
g_0 = shell thickness, in.
g_1 = maximum hub thickness, in.
g = intermediate hub thickness, in.
h = hub length, in.
K = A/B
M_h = moment on a unit sector of hub, at any point, lb. Subscripts 0 and 1 refer to this moment at the small and large ends of the hub, respectively
M_r = radial moment at any cylindrical section of the ring, per unit circumference of the section, lb. Subscripts 1 and 2 refer to this moment at the inside and outside diameters of the ring, respectively
M_t = tangential moment at any point on a radial section of the ring per unit radius, lb. Subscripts 1 and 2 same as for M_r
P = shear on a unit sector of hub, at any point, lb per in. Subscripts 0 and 1 same as for M_h
p = hydrostatic pressure, lb per sq in.
Q = shear on a cylindrical section of the ring, per unit circumference of the section, lb per in.
r_1 = inside radius of ring, hub, and shell, in.
r_2 = outside radius of ring, in.
r = radius to any point in ring, in.
t = ring thickness, in.
W = total bolt load, lb
W_1 = equivalent bolt load, or total force applied at the outside diameter of the ring, and (oppositely) at the inside diameter of the ring, which multiplied by the radial breadth of the ring equals the total moment loading on the ring, lb
w = nondimensional radial displacement of hub or shell at any point, $= y/r_1$
x = axial distance along hub or shell, measured from junction surface between them, and positively in direction toward ring, in.
y = radial displacement of hub or shell at any point, in. (positive away from axis)
z = axial displacement of ring at any radius, in. (positive toward hub)
α = taper factor for hub $= (g_1 - g_0)/g_0$
β = shell modulus $= \sqrt[4]{3(1-\nu^2)/r_1^2g_0^2}$
θ = rotation of element of junction surface between hub and ring
κ = hub modulus $= 12(1-\nu^2)\, h^4/r_1^2g_0^2$

ν = Poisson's ratio; assumed value in design formulas is 0.3

ξ = nondimensional axial distance along hub = x/h

Tapered-Hub Flange Without Hydrostatic Pressure (8)

The loading and dimensions for the ring are indicated in Fig. 3. According to the Poisson-Kirchoff theory, the deflection of a flat plate with axial symmetry and no distributed load is given in polar coordinates by

$$\left(\frac{d^2}{dr^2} + \frac{1}{r}\frac{d}{dr}\right)\left(\frac{d^2}{dr^2} + \frac{1}{r}\frac{d}{dr}\right)z = 0 \qquad [1]$$

By solving this equation and differentiating the expression for z the appropriate number of times, equations for M_r, M_t, and Q are obtained. The complete solution obviously has four integration constants; only three boundary conditions are known so that, to eliminate all four constants, it is necessary to express a relation between two elastic conditions determined by the solution of Equation [1]. The most convenient relation, in so far as the subsequent analysis is concerned, is between M_{r1} and θ; it may be expressed by the equation

$$M_{r1} = -\frac{K^2 - 1}{\frac{1+\nu}{1-\nu}K^2 + 1}\left((1+\nu)\frac{2D}{B}\theta + \frac{W_1}{2\pi}\left[\frac{1}{2} + \frac{(1+\nu)}{(1-\nu)}\frac{(K^2)}{(K^2-1)}\log_e K\right]\right) \qquad [2]$$

Also

$$M_{t1} = -\frac{K^2+1}{K^2-1}M_{r1} - \frac{W_1}{2\pi}\left[\frac{1-\nu}{2} + \frac{(1+\nu)K^2}{K^2-1}\log_e K\right] \qquad [2a]$$

The three known boundary conditions which serve in the derivation of Equation [2] are

$$\left.\begin{aligned} z_1 &= 0 \\ M_{r2} &= 0 \\ Q &= -W_1/2\pi r \end{aligned}\right\} \qquad [3]$$

The hub loading is also shown in Fig. 3. The stresses and deformations are the same as those for a beam with varying section on an elastic foundation, if we consider a strip of the hub having unit circumferential dimension. Whether this dimension be measured at the middle, inside or outside surface is relatively unimportant; in this discussion, to preserve conformity with the ring analysis, the measurement is taken at the inside surface. Then the radial displacement at any point is given by

$$\frac{d^2}{dx^2}\left(g^3\frac{d^2y}{dx^2}\right) + \frac{12\,(1-\nu^2)\,g}{r_1^2}\,y = 0 \qquad [4]$$

For convenience, this may be written in nondimensional form as

$$\frac{d^2}{d\xi^2}\left[(1+\alpha\xi)^3\frac{d^2w}{d\xi^2}\right] + \kappa\,(1+\alpha\xi)\,w = 0 \qquad [4a]$$

by the substitutions defined in the nomenclature. It should be noted that the ratio $h^4/r_1^2g_0^2$, which is the essential part of κ, plays, with α, the most important rôle in the strength of the hub.

When g is variable, an exact solution is obtainable in terms of Bessel functions (9). In the present development, a close approximation is obtained by the strain-energy method with three parameters (a_1, a_2, a_3) which are so related that, if a_1 is used alone, a first approximation is obtained and all boundary conditions are satisfied; if a_1 and a_2 are used, a second approximation is obtained with all boundary conditions satisfied; and similarly for a_1, a_2, and a_3, used together (10). With regard to the boundary conditions, it may be remarked that here again they are four in number, since we are dealing with a fourth-order equation. They may be taken as: The radial displacement at the large end, moment at the large end, moment at the small end, and shear at the small end, in which cases the first is known (zero) and the remaining three are, for the present, unknown. In harmony with the nondimensional notation used in Equation [4a], these three unknown conditions may be replaced by the three quantities A_0, A_1, and B_0, which represent respectively the dimensionless curvature $d^2w/d\xi^2$ at the small end of the hub, that at the large end of the hub, and the dimensionless curvature gradient at the small end of the hub. Then, as explained in the authors' complete report (8), w can be written as a polynomial in powers of ξ, with a_1, a_2, a_3, A_0, A_1, and B_0 appearing in the coefficients; and equations can be found which determine a_1, a_2, and a_3 in terms of A_0, A_1, and B_0 for any given κ and α (i.e., any given hub proportions) and make the total energy of the strained hub, with its loads, a minimum. Coincidentally, Equation [4a] is approximately satisfied. This step is tantamount to solving Equation [4a] for w in terms of three unknown constants of integration, the fourth being zero ($w_1 = 0$). From the result, it is possible to compute slopes, moments, and shears by successive differentiation.

The shell has constant thickness g_0 and extends indefinitely from the hub. Using the same elastic theory as for the hub, two of the constants of integration vanish, and

$$y = e^{\beta x}\,(c_5 \sin \beta x + c_6 \cos \beta x) \qquad [5]$$

where $\beta = \frac{\sqrt[4]{\kappa/4}}{h}$, and x, it must be remembered, is now negative. Here again, the elastic conditions of higher order, such as slope and moment, are obtained by successive differentiation.

The analysis of the three separate parts of the flange is now complete, but there are five unknown constants in the equations, and these must either be evaluated or eliminated before numerical results can be obtained that will be consistent for the flange as a whole. On opposite sides of the shell-hub interface, the displacements, slopes, moments and shears are mutually identical; therefore, four equations exist whereby c_5, c_6, A_0, and B_0 may be expressed in terms of A_1. Having taken this step, it is then possible to express the slope θ, moment M_{h1} and shear P_1 at the large end of the hub, in terms solely of A_1. Finally, since $M_{h1} - 1/2P_1t = M_{r1}$, the quantities θ, M_{h1} and P_1 may all be substituted in Equation [2] and the latter then solved for A_1, giving the equation

$$A_1 = -\frac{2(1-\nu^2)\,h^2}{Eg_1^3r_1}MX \qquad [6]$$

where M and X are defined following Equation [10]. The resulting relation is the key to the derivation of the design formulas which are presented in a later paragraph.

The mathematical articulation of the three parts of the flange, as just outlined, involves an excessively large amount of computation whenever a numerical problem is to be solved. However, by grouping all terms in the final formula for A_1 which contain the parameters a_1, a_2, a_3 and constants A_0 and B_0 into two factors F and V, the first of which is proportional to P_1/A_1 and the second to θ/A_1, and plotting curves of F and V with α and κ (or their equivalents in hub dimensions) as arguments, a moderate amount of systematic computation in the preparation of the charts is substituted for many hours of labor on individual, unrelated design problems. The F and V factors appear in the design formulas, and are plotted in Figs. 4 and 5. In one case they apply to the integral type of flange that has just been ana-

lyzed; in the other, they are for loose flanges, where $A_0 = B_0 = 0$. In either event, they include the case of the uniform-hub-thickness flange, where $\alpha = 0$.

With regard to the shear force P_1 which enters into the determination of A_1, it should be noted that, theoretically at least, it can be determined either by differentiating w three times or integrating it once. Actually, due to the approximate nature of the strain-energy method, the two results are never identical. It is reasonable to suppose, however, that a single integration would introduce a smaller error than three successive differentia-

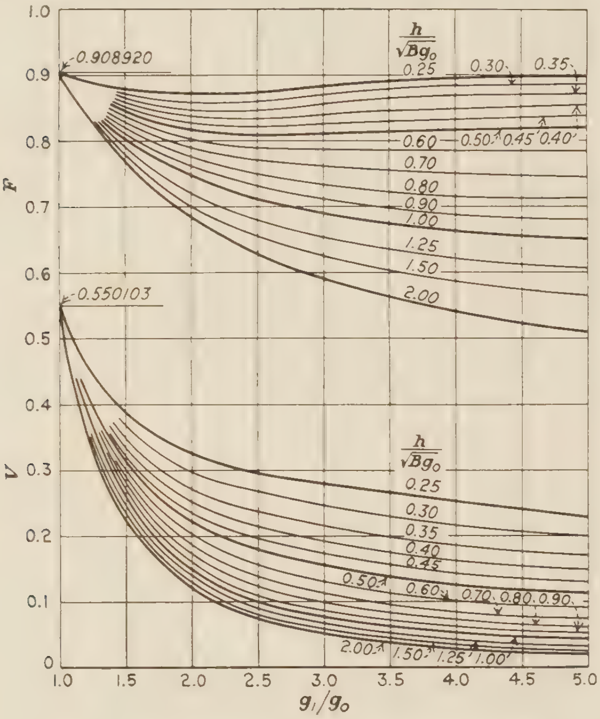

Fig. 4 Values of F and V for an Integral Flange

tions, and comparison of numerical solutions by the precise and strain-energy methods bears out this assumption. The authors have accordingly used the following expression for P_1 in the detailed mathematical development:

$$P_1 = \frac{E}{r_1^2} \int_0^h gy dx + P_0 \qquad [7]$$

Development of Design Formulas

For design and inspection purposes, a detailed analysis of the elastic conditions in all parts of the flange is superfluous, and the requisite data for information and guidance should be consolidated into a few usable formulas for stresses that may possibly be critical. Such formulas would be expected to cover conventional practice, or conservative extensions beyond present conventional design, but always with the reservation that new designs of more radical proportions might possess critical sections that would only come to light through the detailed analysis. All evidence indicates that for a flange with straight hub, the critical stresses are the radial and hoop stresses at the inside diameter of the ring, and the axial hub stress at the surface of junction with the ring. When the hub tapers in the manner assumed in this paper, the same critical stresses may be expected with the exception that, when the angle of taper increases beyond a certain limit, relative to the other hub proportions, the hub becomes so much more rigid than the shell that the location of the critical axial stress in the hub may be displaced from the large toward the small end or even into the shell. The question of the location and magnitude of this critical stress is of the first importance, and a careful study of stress distribution was made for the entire range of hub proportions covered in the charts for F and V, shown in Figs. 4 and 5, to determine under what circumstances a correction factor should be applied to the stress at the large end of the hub, so as to obtain the true maximum stress. It was found that the maximum axial stress always occurred either at one end of the hub or the other; consequently, it is a simple matter to compute its value by using, for the hub moment, either M_{h1} or M_{h0}, according to the location of the critical section. This has been done in design formula [8], where the factor f has been introduced to make the appropriate correction, if any, in the stress. One exceptional condition arises: When α and κ are such that the bending stresses at both ends of the hub are approximately equal, slight oscillations in the values of stress at points along the hub make f somewhat greater than unity. This has been taken account of, in preparing the chart for f shown in Fig. 6, by an adjustment of the lower end of the curves in the vicinity of $f = 1$.

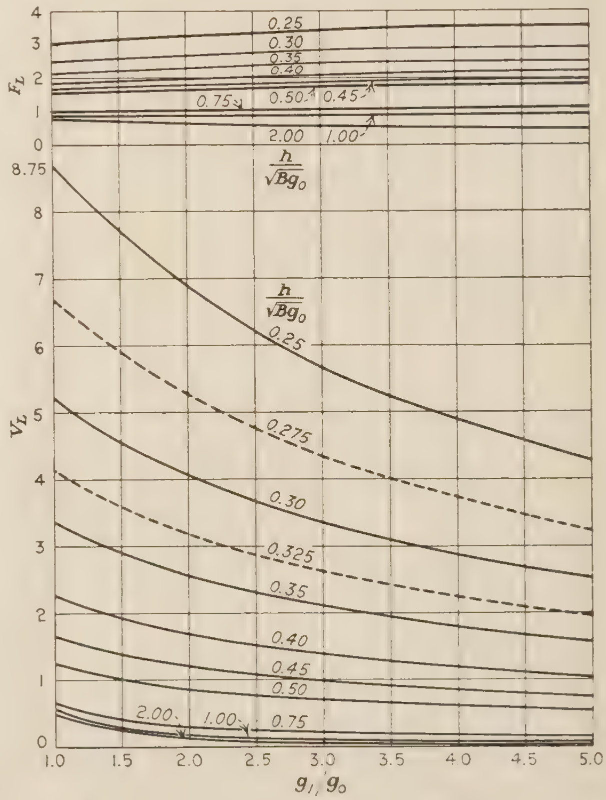

Fig. 5 Values of F and V for a Loose Flange

(Subscript L denotes values of F and V are for a loose flange.)

In the case of loose flanges, an investigation of hubs over the ranges of proportions considered in this paper brought out the fact that the maximum bending stress always occurs at the large end of the hub, consequently $f = 1$ for loose flanges.

In accordance with the foregoing principle, three design formulas have been derived from Equation [6] for computing the maximum axial stress in the hub (or shell), the radial stress in

the ring at its inside diameter, and the corresponding hoop or tangential stress. The first of these results directly from substitution of Equation [6] in

$$M_{h1} = \left[\frac{EI}{12(1-\nu^2)}\,\frac{d^2y}{dx^2}\right]_1 = \frac{Eg_1{}^3 r_1 A_1}{12(1-\nu^2)\,h^2}$$

dividing by the section modulus $g_1{}^2/6$ according to the simple flexure theory, and multiplying by the factor f, which is the ratio of the maximum axial bending stress to the axial bending stress at the junction of the hub and ring. The second results from substitution of M_{h1} and P_1 in the equation $M_{r1} = M_{h1} - \frac{1}{2} P_1 t$, followed by the usual conversion from moment to extreme fiber stress, to which is added the radial stress due to the shear P_1 assumed to be uniformly distributed through the ring thickness. The third is obtained exactly as the second with the added use of Equation [2a]. In this third formula, the hoop stress due to P_1 is added. Finally, it is assumed that $\nu = 0.3$ and the

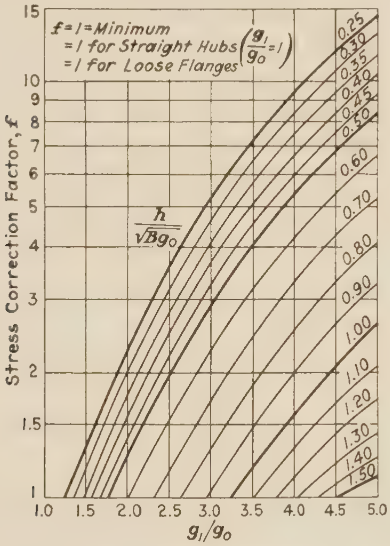

Fig. 6 Values of Stress-Correction Factor f

logarithmic base is changed from e to 10 to facilitate slide-rule computation. Then, using the special design notation, these stresses are

$$S_H = fMX/g_1{}^2 \ldots\ldots [8]$$

$$S_R = \left[1 + 1.33F\,\frac{t/g_0}{\sqrt{B/g_0}}\right] MX/t^2 \ldots\ldots [9]$$

$$S_T = (MY/t^2) - ZS_R \ldots\ldots [10]$$

where S_H = maximum axial stress at outer surface of hub or shell, lb per sq in.

S_R = radial stress at the inside diameter of the ring, in ring face next to hub, lb per sq in.

S_T = hoop stress coincident with S_R, lb per sq in.

M = Wa/B

f = ratio of S_H to axial stress at outer surface of hub where hub joins flange = stress-correction factor. Values are plotted in Fig. 6 for g_1/g_0 from 1 to 5, and $h/\sqrt{(Bg_0)}$ from 0.25 to 1.50

F, V = plotted in Figs. 4 and 5 for the same range as in Fig. 6

$$X = \frac{1}{\dfrac{1}{T}\left(1 + \dfrac{t/g_0}{\sqrt{B/g_0}}F\right) + \dfrac{V}{U}\,\dfrac{(t/g_0)^3}{\sqrt{B/g_0}}}$$

$$T = \frac{3K^2\left(1 + 2\,\dfrac{1+\nu}{1-\nu}\cdot 2.3026\log_{10}K\right) - 3}{\pi(K-1)\left(1 + \dfrac{1+\nu}{1-\nu}K^2\right)}$$

$$U = \frac{3K^2\left(1 + 2\,\dfrac{1+\nu}{1-\nu}\cdot 2.3026\log_{10}K\right) - 3}{\pi(1+\nu)(K^2-1)(K-1)}$$

$$Y = \frac{1}{K-1}\left[\frac{3}{\pi}(1-\nu) + \frac{6}{\pi}(1+\nu)\,\frac{K^2}{K^2-1}\cdot 2.3026\log_{10}K\right]$$

$$Z = \frac{K^2+1}{K^2-1}$$

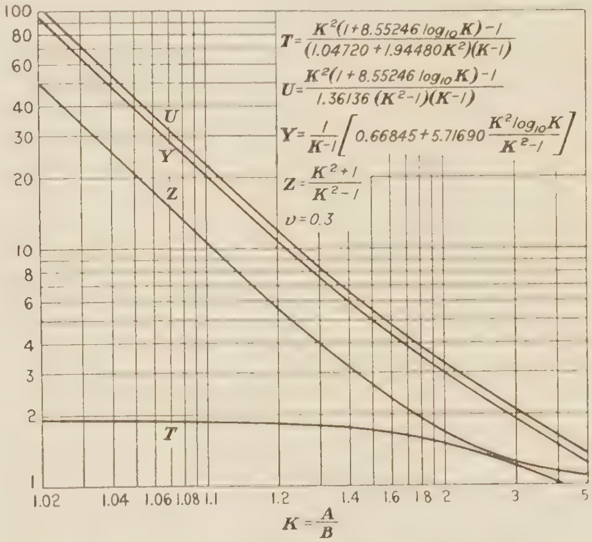

Fig. 7 Values of T, U, Y, and Z When $\nu = 0.3$

Functions of K are plotted in Fig. 7. It should be noted that in the case of loose-ring flanges, there is no hub, consequently S_H and S_R as given by Equations [8] and [9] equal zero.

Tapered-Hub Flange With Hydrostatic Pressure and No Bolt Load

There is an apparent paradox in the title of this section, in that the externally applied forces are not balanced in the axial direction. Actually, the axial pull on the shell may be thought of as balanced by a virtual pull on the contact face of the ring, upon which is superposed a couple of sufficient magnitude to give a resultant pressure on the contact face; and since the stress effects of this couple are completely determined by the methods given earlier in this paper under "Analysis of Stress Distribution," the hydrostatic end force on the shell and the virtual pull on the ring face are the only axial loads that need be considered here. It must further be observed that point O shown in Fig. 3, can no longer be considered as fixed, since the hydrostatic pressure tends to stretch both hub and ring, whereas in the method given earlier in this paper under "Analysis of Stress Distribution" the shearing action at the interface tends to stretch one part and shrink the

other, so that the net effect can, with some justification, be disregarded. With these preliminaries, a stress analysis will now be outlined.

The radial force acting outward on the ring at its inside diameter is $p - P_1/t$ per unit area, and the radial displacement of point O' shown in Fig. 3 may be found by the usual thick-cylinder analysis. The displacement y_1 of point O is greater than this by $-{}^1/_2\ \theta t$; this gives a relation between y_1, P_1, and θ. Secondly, the rotation between the hub and the ring at O is found by letting $W_1 = 0$ in Equation [2] and solving for θ; this gives a relation between θ and M_{r1}, or θ, M_{h1}, and P_1. The hub and shell equations are identical with Equations [4] and [5] except that the right-hand members have a constant term proportional to p/E which gives, in the solution for y, the membrane expansion due to p with discontinuity effects neglected. All told, there are six constants of integration (four in the solution of the hub equation and two in that for the shell); and since there are four identical elastic conditions at the shell-hub interface and two independent relations established for the ring, the necessary and sufficient equations exist for evaluating them.

Unfortunately, the computations for a single problem are extremely laborious; however, it would be possible to derive a set of F and V values analogous to those presented previously in this paper, in which the combined rotation and expansion of the ring are taken into account, and which could be used in simplified formulas like Equations [8], [9], and [10], but with M replaced by p, to compute the first and second peaks of stress caused by the internal pressure.

It may also be suggested that, since the discontinuity stresses due to pressure are apt to be much smaller than those due to bolt pull, it is not necessary to compute them with any great precision. Suppose, for a first approximation, that the tapered hub and shell are replaced by a shell of constant thickness g_0, and that the ring is wide enough to prevent expansion of this assumed hub at its constrained end. If there is no rotation of the ring, the existence of internal pressure causes a large positive moment at the junction with the hub, which is of no consequence as it is counteracted by a negative moment at the same location due to bolt pull; furthermore, the first peak of negative moment due to internal pressure is so small as to be inconsequential. On the other hand, if we permit the end of the assumed hub to rotate freely, at the same time constraining it against expansion, we obtain a zero moment at the junction of hub and ring, and a negative moment at some distance from this point, which is in general of the order of magnitude of the negative peak of moment that occurs in the actual hub-shell combination under pressure from within. The extreme fiber stress due to this moment may be combined with the stress due to the hydrostatic end force, and with the maximum bending stress in the hub due to bolt pull, if the latter occurs at the small end of the hub, to get an approximate value of the maximum longitudinal stress due to both internal pressure and bolt pull. If the maximum longitudinal hub stress due to bolt pull alone occurs at the large end of the hub, it is considered unlikely that a much greater longitudinal stress, due to combined bolt pull and internal pressure, occurs at any point whatever.

The mathematical expression for the maximum longitudinal stress in the hub, caused by internal pressure, is greatly simplified by this approximation. Using

$$y = e^{\beta x}\,(c_9 \sin \beta x + c_{10} \cos \beta x) + \left(1 - \frac{\nu}{2}\right) \frac{r_1^2 p}{g_0 E}$$

and its first and second derivatives, and specifying that $y = M_h = 0$ when $x = 0$, it is found that the integration constants become

$$c_9 = 0 \text{ and } c_{10} = -\left(1 - \frac{\nu}{2}\right) \frac{r_1^2 p}{g_0 E}$$

Substituting these in the equation for the moment and its first derivative, the maximum moment in the hypothetical hub, due to pressure, is found to occur at a distance $x = -\pi/4\beta$ from the back of the ring, and its value is

$$M_h = -\left(1 - \frac{\nu}{2}\right) \frac{pe^{-\pi/4}}{(2\sqrt{2})\ \beta^2}$$

The corresponding longitudinal tensile stress in the outer surface of the hub, assuming $\nu = 0.3$ is

$$S_1 \approx 0.5\ r_1\ p/g_0$$

In other words, the maximum stress in the outer fibers of the hub, due to bending caused by internal pressure, is of the same magnitude as the direct tensile stress in the shell due to the hydrostatic end force.

Illustrative Problems

A few illustrative problems are given as an aid to a clear understanding of the charts and design formulas. In the second and third problems, a calculation of the bending stresses along the hub and shell has been made, showing the separate effects of bolt load and hydrostatic pressure. This requires the use of formulas and methods which are only outlined in the present paper, but are given in complete detail in the authors' report, previously referred to (8).

Example 1. Given an integral flange with the following dimensions: $A = 44^1/_8$ in., $B = 36^5/_8$ in., $t = 2^{15}/_{16}$ in., $g_0 = 1$ in., $g_1 = 1^1/_2$ in., $h = 3^1/_8$ in. Find the critical stresses S_H, S_R, S_T, assuming that the bolting is such as to give a ring moment of 402,000 in-lb.

The design factors are: $M = 10976$, $K = 1.2048$, $g_1/g_0 = 1.5$, $h/\sqrt{Bg_0} = 0.5164$, $t/g_0 = 2.9375$, $\sqrt{B/g_0} = 6.05186$. From Fig. 4, $F = 0.847$, $V = 0.310$, and entering Fig. 7 with K, it is found that $T = 1.835$, $U = 11.91$, $Y = 10.4$, $Z = 5.60$. According to Fig. 6, $f = 1$. By calculation, $X = 1.139$, and the three stresses that may be critical are, in round numbers: $S_H = 5500$ lb per sq in., $S_R = 2200$ lb per sq in., and $S_T = 700$ lb per sq in.

This flange is designed to carry an internal pressure of 75 lb per sq in., which gives a longitudinal membrane stress of only 460 lb per sq in. at the large end of the hub, negligible in comparison with S_H. At the small end of the hub the longitudinal membrane stress is 700 lb per sq in., which, as previously stated, may be taken as a rough indication of the maximum bending stress that may be expected from the internal pressure.

If we compare the stress conditions in this flange as just computed with those in an identical flange not secured to a shell, i.e., a loose flange with hub, we find that F and V have new values. These, as obtained from Fig. 5 are $F_L = 1.52$ and $V_L = 0.98$. This changes X to 0.773, and the three stresses become $S_H = 3770$ lb per sq in., $S_R = 1950$ lb per sq in., and $S_T = 2290$ lb per sq in. If the hub of the loose flange is made progressively shorter, it will be found that S_H and S_R approach zero, while S_T becomes the critical stress and approaches its maximum value of 13,230 lb per sq in.

Example 2. A filter shell flange has the following dimensions: $A = 127$ in., $B = 120^1/_4$ in., $t = 2^{15}/_{16}$ in., $g_0 = {}^5/_8$ in., $g_1 = 1^1/_8$ in., $h = 3^1/_8$ in., bolt-circle diameter $= 124^1/_2$ in., outside diameter of gasket = 123 in., inside diameter of gasket $= 121^1/_4$ in. Thirty-six $1^1/_2$-in. bolts are used, with an allowable stress of 20,000 lb per sq in. Using a slight modification of the method specified in the A.S.M.E. Code for Unfired Pressure Vessels for computing the effective loading on the ring, in accordance with the practice of certain designers, the equivalent ring moment Wa is assumed equal to 903,000 in-lb.

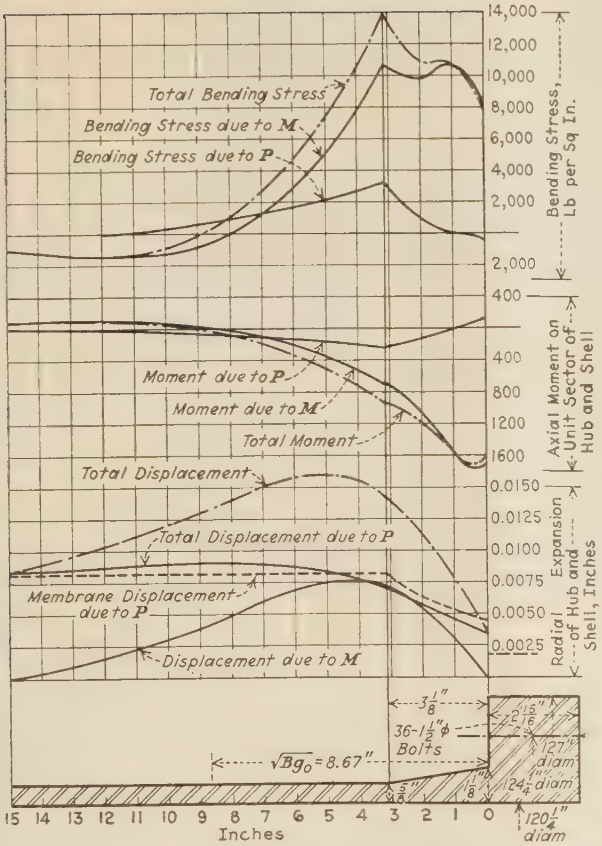

Fig. 8 Graphical Results of Examples 2 and 3

The various factors in the design formulas are then as follows: $K = 1.0561$, $g_1/g_0 = 1.8$, $h/\sqrt{Bg_0} = 0.3605$, $F = 0.852$, $V = 0.293$, $T = 1.90$, $U = 39.0$, $Y = 35.2551$, $Z = 18.3295$, $t/g_0 = 4.7$, $\sqrt{B/g_0} = 13.8708$, $X = 1.3427$, $M = 7509.36$, and $f = 1.4$. The foregoing factors have been computed either directly or from plotted values of a_1/A_1, a_2/A_1, etc., since it was desired to include a detailed analysis of hub stress in this and the following problem, for which accurate values of the design factors are essential. Stresses that may be critical are, in round numbers: S_H = 11,000 lb per sq in. (at small end of hub), S_R = 1600 lb per sq in., and S_T = 750 lb per sq in. It is quite obvious that in this particular flange the ring stresses are negligible.

Using the detailed stress analysis in the authors' complete report (8), the displacement, bending moment, and bending stress in the hub and shell have been computed for selected points, and the corresponding curves are shown in Fig. 8. These curves bring out clearly the stiffening effect of the tapered hub, the effect of the taper in shifting the maximum moment and bending stress away from the large end of the hub, and the small value of the shell as a strengthening element after a certain length has been reached. No curves are shown for the ring, since the ring stresses are not critical and the ring proportions are such that it rotates with practically no change of shape.

Example 3. The flange of example 2 is subjected to an internal pressure of 50 lb per sq in. Again using the formulas in the complete report, curves of displacement, moment and bending stress are shown in Fig. 8 for the effect of hydrostatic pressure with bolt pull absent. The dashed line indicates the membrane expansion of the three elements of the flange, treated as independent members without discontinuity stresses. The slope of the solid displacement curve at the junction of hub and ring illustrates the rotation of the ring due to hydrostatic pressure alone, in which respect the behavior differs markedly from that of a cylindrical vessel with reinforcing ring at a distance from its end. The moment at the large end of the hub is reduced, and the maximum occurs not at that point but at the second peak, where its sign reverses so that the bending stresses due to bolt pull and hydrostatic pressure are additive.

When the effects of bolt pull and internal pressure are combined, it is found that the latter adds considerably over 25 per cent to the bending stress caused by the former; thus, illustrating the importance of an investigation of pressure effects when the two components of bending stress have additive maxima. It should also be noted that the total expansion reaches a maximum of about 200 per cent of the membrane expansion alone. However, since the membrane hoop stress in the shell, figured by the customary simple rule, is somewhat less than 5000 lb per sq in., the actual maximum hoop stress is not excessive when compared with the maximum bending stress. Specifically, the total stresses at the junction of shell and hub are as follows, using Hooke's law for two dimensions:

Axial stress, outer surface = longitudinal membrane stress + bending stress = 16,575 lb per sq in.

Axial stress, inner surface = longitudinal membrane stress — bending stress = —11,765 lb per sq in.

Hoop stress, outer surface = (E × total hoop strain) + ν (axial stress in outer surface) = 12,068 lb per sq in.

Hoop stress, inner surface = (E × total hoop strain) + ν (axial stress in inner surface) = 3565 lb per sq in.

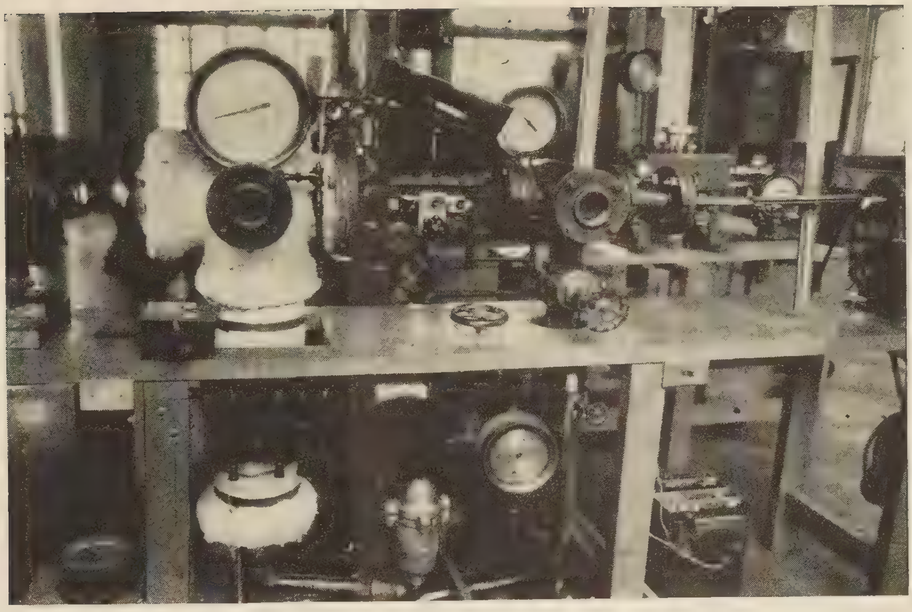

Fig. 1 The Apparatus Used in the Experiments

The Condensation of Flowing Steam
Part I—Condensation in Diverging Nozzles

By J. I. YELLOTT,[1] HOBOKEN, N. J., and C. K. HOLLAND,[2] NEW YORK, N. Y.

The authors discuss the apparatus and method used in determining the point of condensation in diverging nozzles. The discussion is restricted to nozzles with very short throats and with angles of divergence greater than 2 deg. As a primary result of the work described, the authors locate the Wilson line for continuously expanding steam at the 4.5 per cent moisture line on the Mollier diagram. Condensation points and sizes of steam droplets are discussed for various pressure and temperature conditions before expansion and for various back pressures.

Nomenclature

THE FOLLOWING symbols are used in this paper. Special notations are explained as the necessity arises:

A = area, sq ft
a = area, sq in.
d = liquid density, lb per cu ft
h = enthalpy, Btu per lb
k = exponent of isentropic expansion for wet steam
m = area ratio, a_2/a_1
p = abs pressure, lb per sq in.
P = abs pressure, lb per sq ft
r = droplet radius, ft
R = gas constant, ft-lb per deg per lb
S = supersaturation ratio = p_c/p_s
t = temperature, F
T = abs temperature, F
v = velocity, fps
V = specific volume, cu ft per lb
x = exponent of isentropic expansion for steam expanding after condensation
β = pressure ratio, p_2/p_1
γ = exponent of isentropic expansion for superheated steam
σ = surface tension, lb per ft
Δh_i = isentropic change in enthalpy, Btu per lb

[1] Assistant Professor of Mechanical Engineering, Stevens Institute of Technology. Jun. A.S.M.E. Professor Yellott received the degree of Bachelor of Engineering in 1931 from Johns Hopkins University after which he returned to the University for two years of graduate work under Prof. A. G. Christie. He received his M.M.E. degree from Johns Hopkins University in 1933 and then became instructor in mechanical engineering at the University of Rochester. He joined the faculty of Stevens Institute in 1934 where in September, 1936, he was advanced to his present grade.

Mr. Holland was graduated from Stevens Institute of Technology in 1934 with an M.E. degree and received his master's degree in 1936. From June, 1934, to June, 1936, he served as instructor in mechanical engineering at Stevens Institute. The data presented in this paper were the basis of his thesis for his M.S. degree.

Contributed by the Fuels and Steam Power Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

δh = loss due to supersaturation, Btu per lb
δt = undercooling, $t_s - t_{ss}$, F

The following subscripts are used:

e = equilibrium expansion or condition
sat = saturated condition
ss = supersaturated condition
c = condensation condition
1 = initial condition before the expansion
2 = final condition after the expansion

Introduction

It has long been known that in rapid expansions steam does not condense when the saturated condition is reached. Instead it continues to expand as in the superheated region, thus becoming supersaturated or undercooled. This condition persists until the steam reaches some lower pressure at which condensation suddenly takes place in the form of a vast number of extremely minute droplets. This phenomenon has been of interest to physicists since the classic researches of C. T. R. Wilson (1),[3] whose cloud chamber is widely used in the study of ionization problems. J. J. Thomson (2) analyzed the work of other important contributors to this field, among whom should be mentioned Aitken, Barus, von Helmholtz, and Sir William Thomson, later Lord Kelvin.

The late H. M. Martin suggested in 1918 (3) that this failure to condense might be of importance in the design of turbine nozzles. It was Martin (3, 4) who applied Wilson's name to the line on the Mollier diagram which marks the loci of the conditions at which condensation actually occurs. Stodola (5, 6) made a number of experiments in this field and originated the optical method which has been used by the authors in the present work. Vol. 2 of Stodola's monumental work on steam turbines contains a detailed discussion of many aspects of this problem. A different approach to the subject was made by Goodenough (7), in which he maintained that two-phase velocities were probably responsible for the peculiar flow coefficients found with wet steam.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

In 1934 Yellott (8) published the results of work done at the Johns Hopkins University under the guidance of A. G. Christie. This work has since been carried forward by J. T. Rettaliata (9). Since 1934 an extensive series of tests has been performed; first at the University of Rochester by Yellott and Gridley, and later at Stevens Institute by the authors. The purpose of this work, part of the results of which are presented in this paper, was to check the accuracy of the original tests and to clarify certain points which were not thoroughly understood. It was soon discovered that an error in the original experimental methods had caused an incorrect location of the Wilson line. Improved apparatus also revealed a number of phenomena which did not appear in the original experiments.

The investigation of the general problem of the condensation of flowing steam is still under way, and it seems desirable to present at this time only the results of the work on diverging nozzles. This phase of the work has been subjected to repeated tests and the results are so consistent that they are considered by the authors to be reliable.

The condensation which occurs in converging nozzles has not yet been studied in sufficient detail to warrant publication of the results which have been obtained. It must suffice to say that condensation can occur in converging nozzles and it is usually accompanied by rapid growth of the droplets. Condensation can occur over a relatively wide range of steam conditions, and, as suggested by Rettaliata (9), a Wilson zone must therefore be introduced to replace the Wilson line.

The Experimental Work

Basis of the Experimental Work. When work was begun on this problem in 1931, it was found that with proper illumination the point of condensation in flowing steam could be seen clearly.

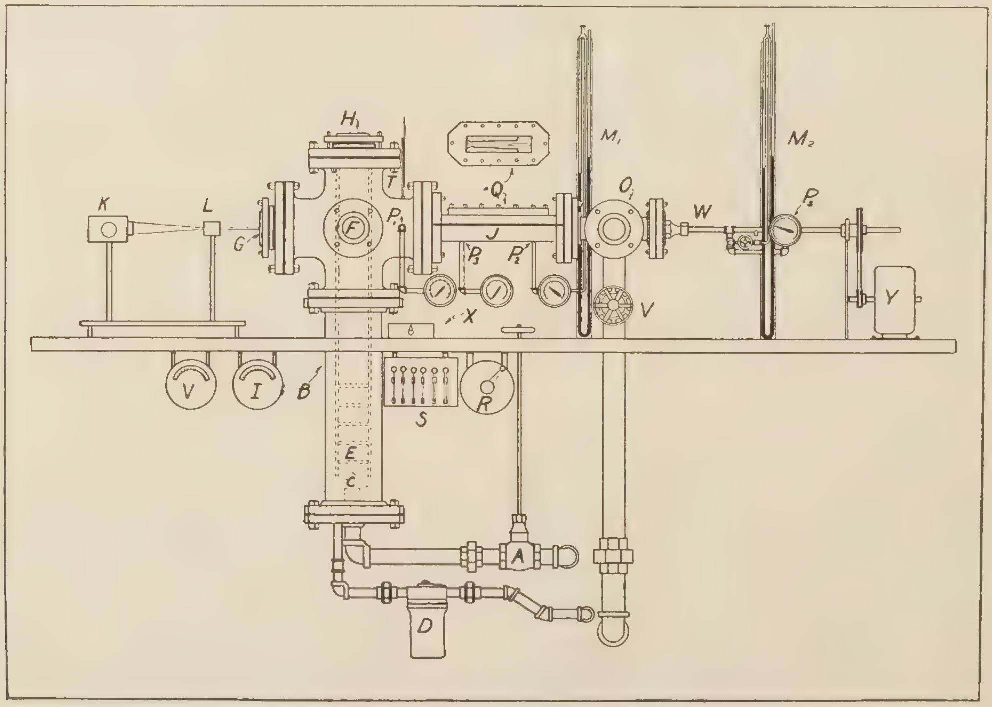

Fig. 2 Details of Steam-Flow Apparatus

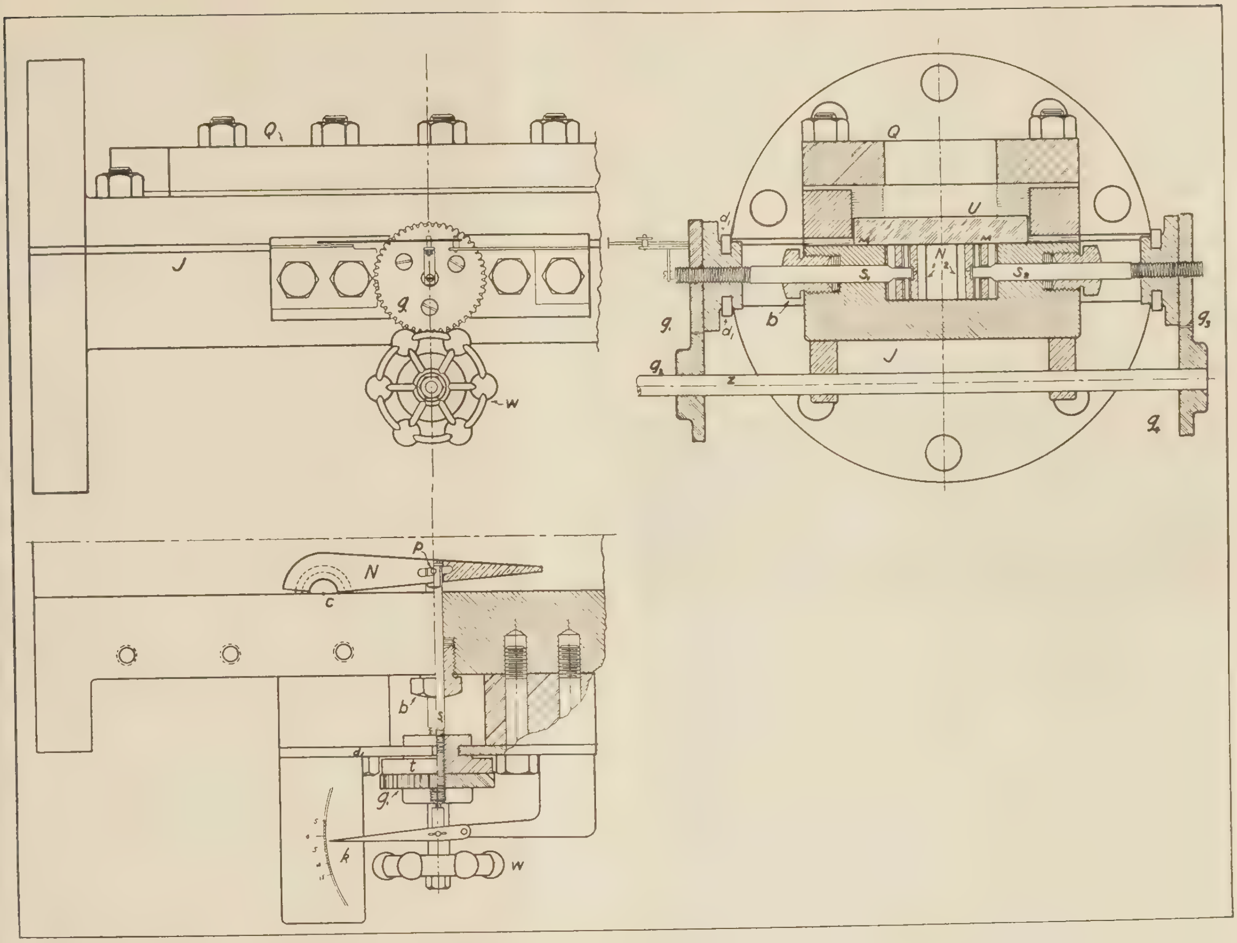

Fig. 3 Details of Nozzle Design

If a beam of intense light were passed axially along the nozzle, the light scattered by the droplets could be observed through a glass window in the top of the nozzle. This principle has been employed in all of the succeeding work, although the apparatus has been considerably improved and the experimental methods have been refined. The static pressure at the condensation point was determined by very small holes in a brass search tube which could be traversed along the axis of the nozzle. A sharp break was found to occur in the pressure-length curve at the point where condensation took place. Because of this fact, condensation points could be located even when the optical method was not employed.

It was noticed that the light scattered by the drops was blue in color and almost completely plane-polarized when observed from a direction normal to that of the incident light. The drops were thus shown to be far smaller than the wave length of the light which was scattered by them. This polarization was frequently used to assist in locating the point at which the condensation occurred. When condensation took place in larger drops or when originally small drops grew to larger size, the nature of the polarization changed.

Description of the Apparatus. The apparatus now being employed is shown in Fig. 1. It is quite similar to that used in the original work (8), but a number of important changes have been made. Referring to the sketch of the apparatus shown in Fig. 2, steam from the laboratory mains enters through a pressure regulator. A cooling jacket around the inlet pipe allows the steam to be thoroughly desuperheated if necessary. Further regulation is accomplished by the globe valve *A*, after which the steam passes into the 6-in. vertical pipe *B*. An inverted metal cone *C* is of some value in removing the larger drops of water which frequently accompany the incoming steam, but the smaller drops do not appear to be deterred by it. Drainage is accomplished by the steam trap *D*.

The electrical superheater *E*, consisting of five nichrome coils supported by porcelain insulators and steel rods, is capable of dissipating about 8 kw. It is controlled by the knife switches *S*, and the input is measured by the voltmeter *V* and the ammeter *I*. Power can be supplied either from the laboratory d-c line at 110 volts or from a small turbogenerator. The voltage supplied by the generator can be controlled by means of the field rheostat *R*, which permits close regulation of the steam temperature.

The steam then passes through the cross which is equipped with glass ports at *F* and *G*. Light from the carbon arc *K* is admitted through *G* and the entering steam can be examined through *F*. The leads from the superheater are brought out through insulated bolts in the top flange *H*. The temperature of the steam is measured by a precision-grade mercury-in-glass thermometer which is inserted in a mercury-filled thermometer well at *T*. This thermometer has been calibrated by the National Bureau of Standards and checked in place by the pressure-temperature relation for saturated steam. When the proper stem correction is applied,

the thermometer gives results which agree within 0.1 F with the saturation temperature when wet steam is passing through the apparatus.

The pressure is measured by a calibrated Bourdon gage or a mercury manometer connected to a $^1/_4$-in. pressure tap at P_1 in the side of the cross. The principal difference between the present apparatus and that used at the Johns Hopkins University (8) lies in the fact that for the earlier work the temperature was measured by a thermometer located at F while the pressure was measured from a $^1/_{32}$-in. tap in the bottom of the nozzle channel at P_3. It was thought at that time that the pressure drop, $p_1 - p_3$, through the entrance to the channel was negligible. This assumption was later found to be erroneous, and because of it the Wilson line as located in 1934 (8) was about 1 per cent too high.

The nozzles are located in the cast-iron channel J, which is shown in detail in Fig. 3. The channel, which is 2 in. wide, 1 in. deep, and 15 in. long, is located in the lower part of the nozzle assembly. The upper part of the assembly is bolted tightly to the lower part, and $^1/_8$-in. rubber-sheet packing is used to prevent leakage. The central portion of the top of the assembly is cut away to accommodate the glass plate U. The plate is a special high-temperature glass, $^5/_8$ in. thick. The glass bears directly on the scraped cast-iron surface MM, and is held down by the cover plate Q. Several thicknesses of sheet packing are used as a gasket between the cover plate and the glass, and leakage at this point is effectively prevented. The use of this double construction has eliminated the glass breakage which frequently occurred in the original apparatus.

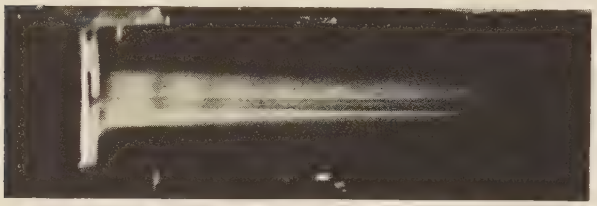

Fig. 4 Flow Through a Rounded-Approach Nozzle
(Steam conditions: p_1 = 60 lb per sq in. abs; t_1 = 306 F; and p_2 = 29 lb per sq in. abs.)

A number of different nozzles have been used in the work. Usually the nozzle is rectangular in cross section and is made by bolting appropriately shaped brass blocks to the walls of the channel. Round nozzles have been made by drilling holes in 1-in.-square steel stock and milling or turning out the superfluous material. Fig. 4 illustrates the flow from such a round nozzle with a rounded approach.

Recently interesting results have been obtained with a variable convergent divergent nozzle, the angle of divergence of which can be varied while the nozzle is being observed through the glass plate. This nozzle was designed by R. Z. Hague of Stevens Institute, class of 1937, and the details are shown in Fig. 3. The nozzle block N is made in two parts which are riveted together. This construction enables N to pivot about c as a center without serious leakage, while approximately the same entering conditions are preserved as the angle of divergence is varied. The block is caused to move by the pin p through the shaft s, which in turn is moved by the threaded member t. Lateral motion of t is prevented by the split collar d_1, and leakage along s is prevented by the packing in the stuffing box b. The gear g_1 fixed to t, is turned by the gear g_2, which is operated by a small hand wheel w. The shaft z transmits the same rotary motion to the gears g_3 and g_4. The other nozzle block N_2 is caused to move by the left-handed threads on the shaft s_2.

The angle of divergence is indicated by the graduations on the dial k and by numbers on the teeth of g_1. The dial was calibrated by means of accurate templates and checked trigonometrically with micrometer and gage-block measurements. The readings from g_1 bear an approximately linear relation to the angle of divergence, which makes possible adjustments which are accurate to within ± 5 min. The angle of divergence can be varied from +16 deg to —5 deg.

The clearance between the blocks N_1 and N_2 and the glass U is about 0.001 in., and the leakage through this space is unimportant. Due to a slight looseness of the pin p, the angle must always be read when the nozzle is being closed. Thus far no other difficulties have arisen with this device.

The back pressure is obtained by a $^1/_{32}$-in. tap at the bottom of the channel at P_2, shown in Fig. 2. This tap is connected by water-filled lines to a combination gage and to a 30-in. mercury manometer. The steam passes out of the apparatus through the side outlet tee O, and through the gate valve V to a condenser. A port mounted at O permits the steam to be observed as it leaves the apparatus.

Static pressures along the axis of the nozzle are obtained by the search-tube W, which is 0.125 in. in diameter. The four pressure taps on the tube are located in a plane perpendicular to the axis of the tube and are about 0.005 in. in diameter. The tube leads to a combination gage O_s, and a mercury manometer M_2. An indicator can also be mounted on the search tube and autographic traverses can be made with the assistance of the motor Y, which is controlled by the switch X. When full illumination of the channel is required the search tube can be reversed and mounted at port G.

The optical system which supplies the illumination consists of a clock-fed carbon arc K, a condensing lens, and a focusing lens L. A water cell is usually used when filters or polarizers are being employed. If the water cell is omitted, the heat from the beam is usually sufficient to prevent fogging of the port G through which the light is admitted. The sight glasses at the ports F, G, and P are pyrex disks, $^1/_2$ in. thick, mounted between $^1/_8$-in. rubber gaskets. The glasses must be cleaned at frequent intervals because of the impurities which accompany the steam. Cleaning can sometimes be accomplished by passing very wet steam through the apparatus.

Review of the Experimental Work. The work at Rochester in 1934 and at Stevens in 1935 was largely experimental in nature, for each new apparatus made visible a number of phenomena which were not observed with the earlier equipment. During 1935, attention was directed to the condensation of wet, saturated, and superheated steam in a typical convergent divergent nozzle. A large number of condensation-pressure measurements were made for initial pressures ranging from 20 to 100 lb per sq in. abs, and temperatures up to 395 F. The range of entropy was 1.62 to 1.767.

It was found at the University of Rochester that variation in the back pressure could play an important part in determining the type of condensation which occurs in diverging channels, and this problem has been investigated more fully.

The use of a sharp-edged orifice revealed the fact that changes in the vena contracta could be observed as the back pressure was reduced below the critical ratio, $p_2/p_1 = 0.55$. With such an orifice, the flow continues to increase as the back pressure is lowered, instead of becoming constant as does the flow from a rounded nozzle. Fig. 4 shows the flow from a rounded-entrance nozzle discharging at a velocity slightly greater than the velocity of sound. The standing pressure waves shown in this picture have been investigated by Prandtl (10) and Emden (11).

It was noticed in all of the work mentioned previously in this paper that back-pressure variations and alterations in the rate of expansion resulted in characteristic changes in the nature of

the condensation. The variable nozzle was therefore designed in order to permit complete control of all the factors involved in the problem. A precision potentiometer has been procured and work is now going forward on the problems of condensation in converging and slowly diverging streams. Correlated work is being done on the problem of measuring supersonic velocities by impact tubes in the hope that eventually velocity coefficients can be established for supersaturated expansions.

It is the purpose of this paper to present the results of the work on convergent divergent nozzles of the type to which, in honor of the inventor, the name "De Laval" is given. The discussion will be restricted to nozzles with very short throats and with angles of divergence greater than 2 deg. It is believed that within these relatively narrow limits the results presented here are reliable. The results should be of value to the designers of apparatus in which these types of nozzles are used, such as the reversing sections of marine turbines. Steam-jet air ejectors and steam-jet refrigerators also use nozzles of this type.

Results of Tests on De Laval Nozzles. The effect of variations in the initial conditions of the expanding steam upon condensation pressure and supersaturation was investigated by measuring the static pressure at the condensation point for a wide range of initial conditions. Most of the measurements were made with a nozzle similar to that shown at the top of Fig. 5. The angle of divergence of this nozzle is about 11 deg and the back pressure could not be reduced sufficiently to make the nozzle flow full at all times. Fig. 6 shows a series of flow illustrations taken with

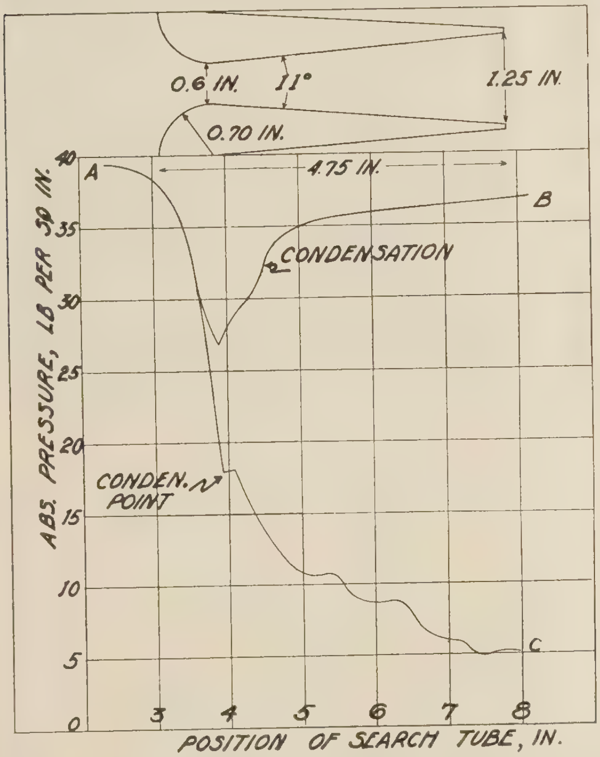

Fig. 5 Typical Pressure Traverse in a Divergent Nozzle
(Steam conditions: p_1 = 40 lb per sq in. abs; saturated; for curve AB, p_2 = 37 lb per sq in. abs; and for curve AC, p_2 = 6 lb per sq in. abs.)

the same initial pressure of 100 lb per sq in., and temperature of 371 F, but with the back pressure varying from 17 to 45 lb per sq in. abs. It will be noted that the flow breaks away from the side of the nozzle at different points, but the nature of the condensation is the same for all cases.

If the back pressure p_2 is raised to within a few pounds of the initial pressure p_1, there is a sharp drop in pressure to the throat of the nozzle and then a rapid recompression up to the back pressure, as shown by curve AB in Fig. 5. Under such conditions, if the steam were initially saturated or very slightly superheated, a slight condensation would occur as the pressure is rising. The point of origin of this condensation is difficult to detect, for the first scattered light is very faint. The term "preliminary condensation" was applied to this type in the earlier paper (8), to distinguish it from the "ultimate condensation" which occurs at the Wilson line.

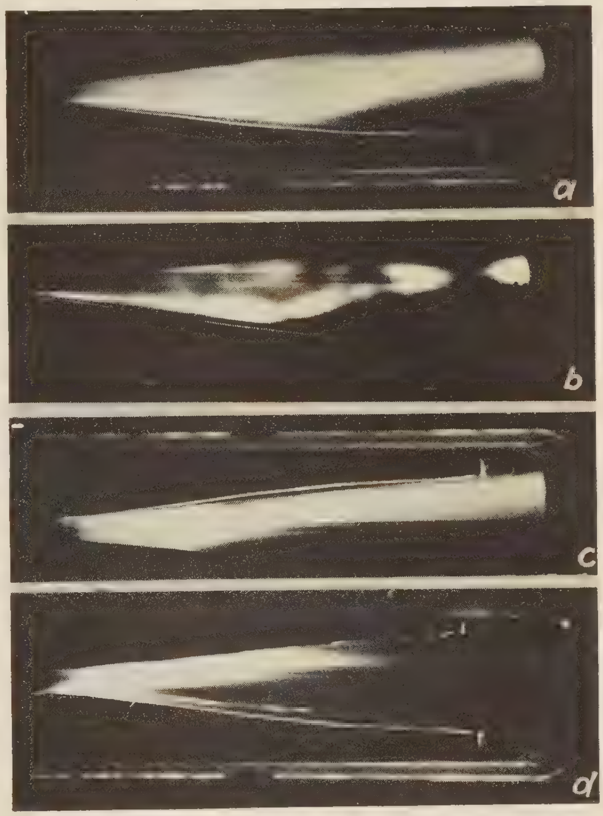

Fig. 6 Flow Through a Fixed Nozzle From an Initial Pressure of 100 Lb per Sq In., and an Initial Temperature of 371 F, but With Varying Back Pressures Illumination From Low Pressure End, Search Tube in Place
(Top: Back pressure = 18 lb per sq in. abs. Second: Conditions the same as for the top illustration but taken through a Polaroid disk to show photoelastic effect. Third: Back pressure = 26 lb per sq in. abs. Bottom: Back pressure = 45 lb per sq in. abs.)

Under the conditions which prevailed when the data for curve A-B, Fig. 5 were obtained, a faint trace of condensation was detected at the 4.5-in. point, about $^1/_2$ in. downstream from the throat. The first color to be seen was an indeterminate saffron, which was followed by violet, purple, green, and saffron again. These colors were visible only when the angle of observation was less than 90 deg to the incident light. If the angle of observation was greater than 90 deg, the entire nozzle seemed to be filled with a whitish-blue color. The scattered light was very slightly polarized at all angles of observation. These optical effects indicate that the droplets are of the same order of magnitude as the light waves which they scatter, from 1.3 to 2.3 $\times$ 10^{-6} ft. The variation in color along the length of the nozzle indicates that the drops are growing, which is natural because the pressure

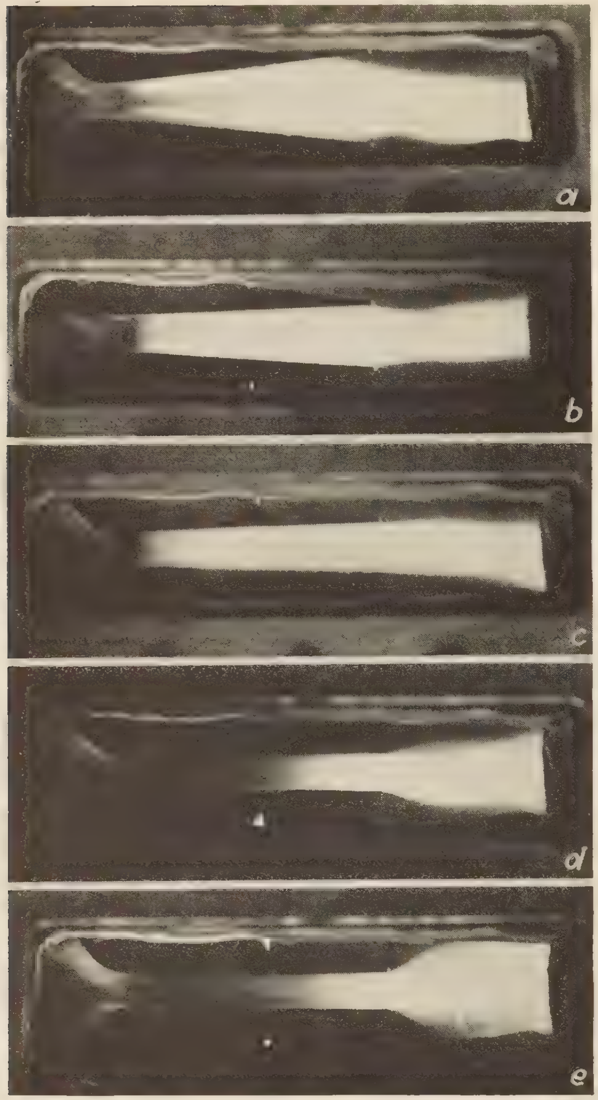

Fig. 7A Flow Through a Variable Nozzle From an Initial Condition of 40 Lb per Sq In. Abs, Saturated; Back Pressure Kept at 10 Lb per Sq In. Abs Except for Last Condition, When It Was Lowered to 7 Lb Abs

(a, Divergence angle set at 13 deg, nozzle overexpanding, steam breaks away from sides. b, Divergence angle 7 deg, overexpanding, Mach wave at exit. c, Divergence angle 4 deg, steam leaves without shock. d, Divergence angle 0 deg, preliminary condensation in nozzle, jet expands beyond exit. e, Divergence angle 0 deg back pressure lowered to 7 lb per sq in. abs. Steam expands to fill channel. Water drops entering with steam reveal eddies beyond exit.)

of the vapor is rising, and consequently the temperature is also increasing. The drops apparently form during the pressure rise, but their temperature does not increase rapidly and they are consequently cooler than the surrounding vapor. Thus, they are able to act as nuclei for further condensation.

If the steam becomes superheated by only a few degrees, the color disappears and the nozzle appears quite empty. When the steam is desuperheated, the pressures remaining constant, the same colors reappear. A small amount of initial moisture has no affect, but a large amount produces a confused picture in which the scattered light is lost.

Fig. 7A shows a series of photographs taken of the variable nozzle, in which the initial condition was held constant at 40 lb per sq in. abs, saturated. The back pressure was kept at 10 lb per sq in. abs except in e, when it was lowered to 7 lb. At an angle of divergence of 13 deg, a, the nozzle was overexpanding and the steam broke away from both sides. At 7 deg, b, the nozzle flowed full, but overexpansion was still present and a Mach wave was visible. This wave could be seen clearly with the eye, but difficulty was experienced in photographing it. Consequently the negative from which b was made was retouched slightly to make the wave stand out more clearly. When the angle was reduced to 4 deg, c, the exit area was approximately correct and the nozzle flowed full without shock. When the sides were made parallel, d, preliminary condensation appeared in the nozzle. Beyond the exit ultimate condensation occurred and the jet expanded but did not fill the channel. With the angle kept at 0 deg, e, the back pressure was reduced to 7 lb abs

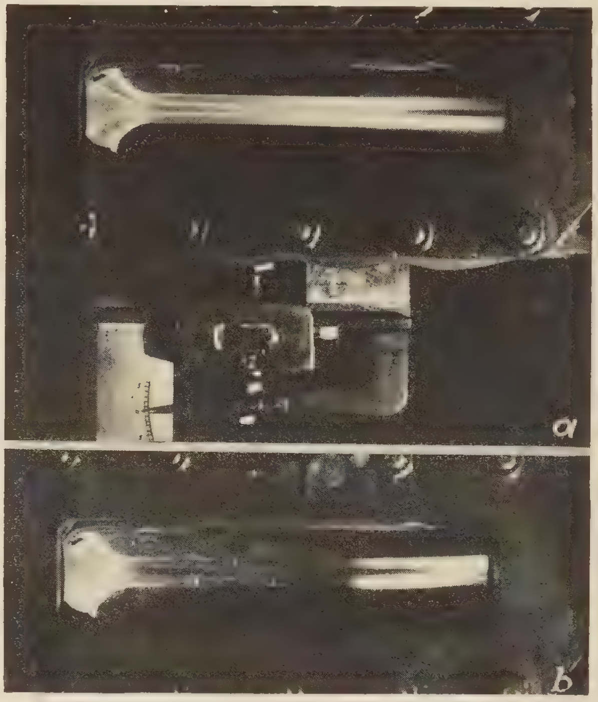

Fig. 7B Top View of Variable Nozzle, Illuminated From High Pressure End, Search Tube in Place

(a, p_1 = 40 lb per sq in. abs, wet; p_2 = 13 lb per sq in. abs; divergence angle set at 0 deg. Preliminary condensation in nozzle followed by ultimate condensation beyond exit. b, Steam conditions same as in a, except initial temperature raised to 285 F. Preliminary condensation absent, ultimate condensation beyond nozzle.)

and the jet expanded until it filled the entire channel. The water drops which were entering the nozzle with the incoming steam revealed an interesting double eddy beyond the nozzle. For the photographs in Fig. 7A the nozzle was illuminated from both the high- and low-pressure ends.

Fig. 7B shows two photographs of the variable nozzle in which the initial steam pressure was kept at 40 lb per sq in. abs while the angle of divergence was kept at 0 deg. The back pressure was 13 lb abs in both cases. In a, the entering steam was wet and preliminary condensation was occurring in the nozzle, with ultimate condensation taking place beyond the exit. In b, the steam temperature was raised to 285 F (18 F superheat) and the preliminary condensation disappeared. For these photographs the nozzle was illuminated from the high-pressure end only, the search tube being mounted on the low-pressure end.

The nuclei upon which the preliminary condensation was

occurring were probably ions, for a charged particle can grow as it follows a path of falling pressure, while an uncharged particle cannot (2). Condensation in nozzles with small angles of divergence is being studied at the present time, and it is hoped that the results will be available shortly.

The results of the condensation-pressure measurements for varying initial conditions are shown on the Mollier diagram in Fig. 8. These values were obtained by making a series of traverses along that portion of the nozzle in which condensation was occurring and noting the pressure at the point where the fog originated. A plot of the pressure against the position along the nozzle axis was also prepared for each test as in Fig. 5, curve *A-C*, and the location of the step in the pressure curve confirmed the visual observation.

By the use of the desuperheater mentioned previously, it was possible to observe the condensation of steam which was initially wet. In spite of the presence of such large quantities of moisture that the beam of arc light could scarcely penetrate to the nozzle, the condensation invariably took place in the same manner as with steam which was initially dry. The familiar blue color was present in the scattered light and the curved condensation surface, concave toward the higher pressure, was also evident. The stream lines of the incoming moisture were frequently visible on the glass top of the nozzle. By throttling the steam with the control valve, the moisture could readily be made to disappear, thus giving visual evidence in support of the theory of the throttling calorimeter. An explanation of the failure of the moisture already present to affect the condensation of new moisture probably lies in the fact that the drops are hotter than the expanding vapor. Hence, the drops are not able to serve as nuclei but will rather tend to evaporate.

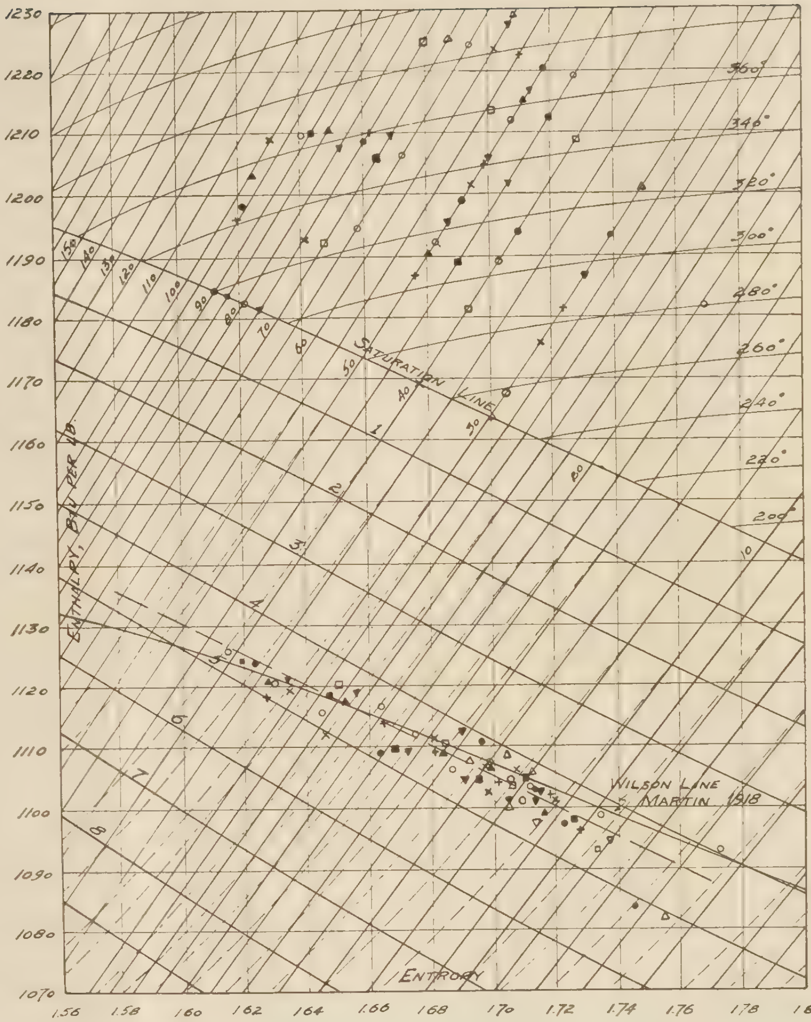

Fig. 8 Mollier Diagram Showing Experimental Results

It will be noticed from Fig. 8 that no initial conditions are shown below the saturation line. Although the entering steam may contain moisture, it behaves as if it were merely a mechanical mixture of saturated steam and drops of water. It is quite possible to have drops of water in an atmosphere of superheated steam, and the presence of water droplets in steam does not insure that the steam is saturated. Additional evidence is necessary, such as the agreement of the temperature of the steam with the saturation temperature at the prevailing pressure. It is probably impossible to measure temperatures in steam below the saturation temperature, because the measuring device will always provide a finite surface upon which condensation will occur.

The points in the superheated region in Fig. 8 were obtained with the aid of the electrical superheater. The points on the 30-lb and 40-lb lines were measured at Rochester while the other points were obtained at Stevens Institute. The agreement in the location of the condensation points would seem to eliminate any question as to possible peculiarities in the steam used in the tests.

The condensation points in Fig. 8 were plotted in the conventional manner shown in the elementary Mollier diagram, Fig. 9*a*. Isentropic expansion is assumed to exist along the axis of the nozzle from the initial condition p_1, t_1, until the condensation pressure p_c is reached at *c*. At this point condensation occurs and there is supposedly an isenthalpic change of condition, accompanied by an increase in entropy, to the equilibrium pressure at *c*. The condensation points, as shown, are plotted as the equilibrium pressures rather than the supersaturated pressures. If they are plotted as the supersaturated pressures, a special Mollier diagram with the supersaturated constant-pressure lines is necessary.

Further expansion takes place from p_e, and it can be seen that there is a loss of availability, δh, because of the increase in entropy which accompanies the condensation.

The procedure just discussed is open to question because it neglects the rise in pressure which has been observed to occur when condensation takes place. Keenan (13) has shown such a pressure rise must occur in a sudden condensation under the conditions which prevail in these nozzles. Likewise, in assuming that the temperature of the vapor rises completely to the saturation value for p_c, we overlook the fact that the droplets formed in the condensation are so small that according to Kelvin's law the vapor

about them is still supersaturated. Both of these questions will be considered later.

The results given in Fig. 8 reveal the important fact that rapid expansions starting on the same entropy line will result in condensation at virtually the same point. Thus, it seems probable

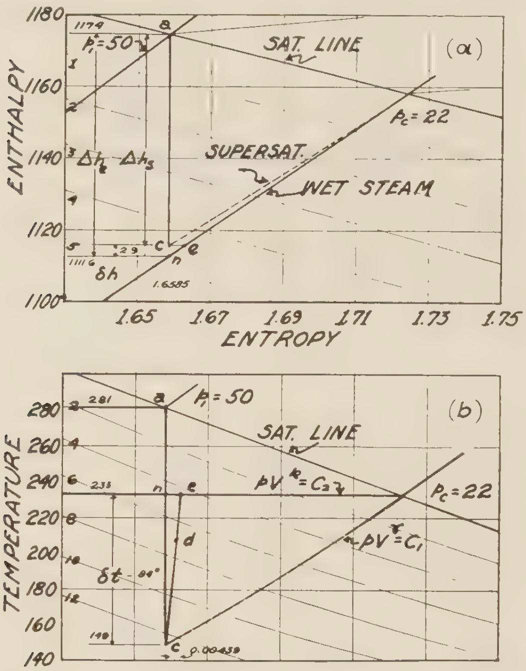

FIG. 9 CONDENSATION POINTS PLOTTED ON ELEMENTARY MOLLIER AND T-S DIAGRAMS

that condensation in such expansions depends only upon the supersaturation and not upon the velocity. For example, the two points on the 1.68-entropy line differed by 35 Btu in their initial enthalpy, but the condensation pressures for the two conditions were almost identical. The upper point, at 70 lb per sq in. abs and 387 F, gave a condensation pressure of about 17 lb per sq in. abs, while the velocity at the condensation point was about 2370 fps. The lower point on the same entropy line is at 50 lb per sq in. abs and 312 F, but the condensation pressure was again at about 17 lb per sq in. abs, although the velocity at the condensation point was about 1985 fps. A still lower point at approximately the same entropy was at the saturated condition of 40 lb per sq in., and this also yielded a condensation pressure of about 17 lb per sq in., with a velocity of about 1670 fps. This relatively wide variation in velocity has apparently had only a small effect, if any, on the condensation. In the same manner, steam with an initial condition of 54 lb per sq in. abs and 360 F, gave approximately the same condensation pressure as steam initially at 30 lb per sq in. saturated.

Since rapid expansions through a De Laval nozzle along any entropy line will result in condensation at the same pressure, regardless of the initial pressure and temperature, the results given in Fig. 8 can be replotted in the form of Fig. 10. This gives the condensation pressure as a function of the initial pressure for steam which is initially saturated. The data for this plot were taken from the dashed line on Fig. 8, which appears to be a fair representation of the experimental values. The scatter of the points is due largely to the difficulty of making accurate determinations of the condensation pressure.

It will be noted from Fig. 10 that the condensation pressure is almost a linear function of the initial pressure for the range along the saturation line which was covered in this work. Whether this relation holds for higher pressures will be learned from tests soon to be performed at Purdue University with a high-pressure apparatus.

Another useful relation is shown in Fig. 11, in which is plotted the ratio p_c/p_1 against p_1 for initially saturated steam. It is apparent that this ratio is always below the critical ratio of approximately 0.55, and consequently ultimate condensation always occurs in the diverging portion of the nozzle and at a velocity above that of sound.

The Wilson line shown in Fig. 8 is apparently the lower limit for supersaturated expansions, for at this condition condensation invariably occurs. In slow expansions, as in nozzles with long throats or small angles of divergence, preliminary condensation can occur at conditions above the Wilson line. The upper limit seems to be at about the 2 per cent moisture line on the Mollier diagram. Thus the Wilson zone, within which condensation

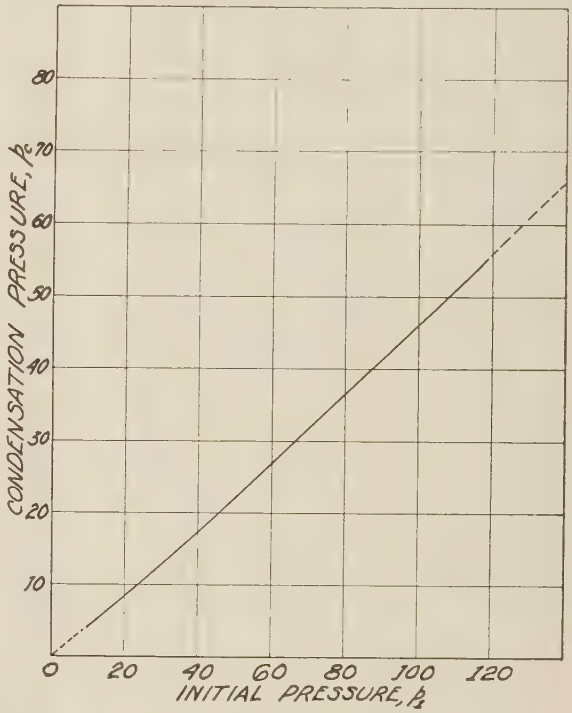

FIG. 10 CONDENSATION PRESSURE AS A FUNCTION OF INITIAL PRESSURE; STEAM INITIALLY SATURATED

must occur, is located between the 2 and 4.5 per cent moisture lines. It is worthy of notice that the Wilson line which Martin predicted from theoretical considerations (3) in 1918 is very close to that determined experimentally.

The supersaturation ratio which exists at various condensation temperatures is plotted against these temperatures in Fig. 12. The supersaturation ratio S is the ratio of the actual condensation pressure p_c to the saturation pressure p_s at the condensation temperature t_c. This temperature is calculated from the initial temperature t_1 by means of the well-known adiabatic relation

$$T_c = T_1(p_c/p_1)^{\frac{(\gamma - 1)}{\gamma}} \quad \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

The values of S calculated for the condensation pressures shown in Fig. 8 lie near the line calculated for the constant drop size

$r = 1.5 \times 10^{-9}$ ft, by means of the Kelvin-von Helmholtz equation

$$\log_e (p_c/p_s) = \log_e S = \frac{2\sigma}{RT_c dr} \quad \ldots\ldots\ldots\ldots [2]$$

where R = gas constant for steam = 1544/18 = 85.7, ft-lb per deg per lb; T_c = condensation temperature, deg F abs; d = density of the liquid at t_c, lb per cu ft; r = drop radius, ft; and σ = surface tension at t_c lb per ft.

The trend of the points in Fig. 12 would seem to indicate that the size of the drops increases with the temperature, but, for several reasons, it is probable that drop sizes calculated from Equation [2] are not reliable.

An average value of the droplet radius for the points shown in Fig. 12 is 1.5×10^{-9} ft. The molecular radius for water vapor is about 4.5×10^{-10} ft, so the calculated droplet radius is about 3.3 times the molecular radius. It is highly improbable that the Kelvin equation is valid for such extremely small drops.

Size of Droplets. The actual size of the droplets formed in ultimate condensation can only be approximated, because they are so much smaller than the wave length of light that they cannot

Fig. 11 Ratio of Condensation Pressure to Initial Pressure as a Function of the Initial Pressure

be measured directly. Because the light scattered by them is blue and almost completely plane-polarized when observed from a direction normal to the incident light, Rayleigh's law (8, Appendix I) indicates that they are "infinitely small dielectric spheres." This means that they are probably from 10 to 1000 times smaller than the wave length of blue light, which would give them a radius of from 1.5×10^{-7} to 1.5×10^{-9} ft.

Rayleigh's law states that the intensity of light scattered by isotropic spheres which are small compared to the wave length of light varies directly as the sixth power of the radii of the spheres. A number of investigators have shown that the light scattered by molecules can be seen against a very black background. Thus, the light scattered by drops with $r = 1.5 \times 10^{-9}$ ft will be about 1300 times more intense than that scattered by molecules. Such light would be readily visible. Light scattered by drops with $r = 5 \times 10^{-9}$ ft would be a million times as intense as molecularly scattered light.

Kinetic theory yields interesting information about the number of molecules contained in the drops which are formed when con-

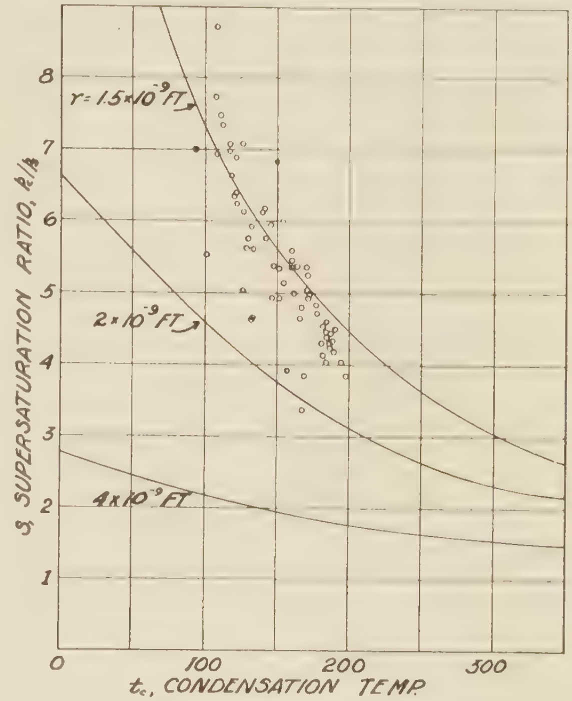

Fig. 12 Supersaturation Ratio Vs Condensation Temperature
(Condensation pressure = p_c; saturation pressure at $t_c = p_s$; $S = p_c/p_s$; and $\log_e S = 2\sigma/RT_c dr$.)

densation occurs. Avogadro's number, the number of molecules per pound molecule of any gas, is 2.75×10^{26}. The molecular weight of water is 18, so the number of molecules per pound is 1.53×10^{25}. The weight per molecule is 6.52×10^{-26} lb. If it is assumed that the molecule is a sphere with radius $r_m = 4.5 \times 10^{-10}$ ft (15, p. 643), the volume of the molecule becomes 3.85×10^{-28} cu ft. The density of the molecule is thus 169 lb per cu ft.

A droplet of water with a radius of 1.5×10^{-9} ft has a volume of 1.42×10^{-26} cu ft. Because of the extremely small size of such a drop, the capillary pressure and the consequent increase in the density should be taken into account. The capillary pressure in pounds per square inch on a droplet of radius r feet, with surface tension σ, is

$$p_{cap} = \frac{2\sigma}{144 \times r} \quad \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

Using a value of $\sigma = 4.8 \times 10^{-3}$ lb per ft, corresponding to 100 F, the capillary pressure in a droplet with $r = 1.5 \times 10^{-9}$ ft is 44,400 lb per sq in. Extrapolating the Keenan and Keyes values for specific volume of compressed liquid (16, p. 75), the density becomes 71 lb per cu ft. The weight of each droplet thus becomes 1.001×10^{-25} lb, and the number of molecules required for a droplet of that weight is 1.57. For several reasons this result is impossible. Obviously, the number of molecules contained in a drop must be integral, and probably a drop, to exist as such, must contain some thousands of molecules. The number 1.57 is inter-

esting, however, in that it might be taken to mean that condensation at the Wilson line consists of the formation of double molecules, as Nernst has suggested (6, p. 1074).

If Keenan's estimate (13) of 5×10^{-9} ft is taken as the droplet radius, the volume of each drop would be 5.24×10^{-24} cu ft, and the weight would be about 3.35×10^{-23} lb. On this basis 514 molecules would be required for such a drop.

It is obvious that such attempts to estimate the drop size from molecular considerations do not lead to any definite results. The concept of surface tension must be abandoned, and replaced by that of molecular attraction. Further optical work, based on the transmitted rather than the scattered light, may yield a more conclusive answer to this question.

The Condensation Process. Speculation as to the physical mechanism by which condensation takes place leads to the difficult conclusion that in some manner the energy released by the moisture at the low temperature t_c is transferred to the remaining vapor, with the result that the temperature of the vapor is raised above that of the supersaturated steam which supplied the heat. This is apparently a violation of the second law of thermodynamics, but it can be shown (6, p. 1036) that the entropy increases during the process, so the law is actually obeyed. The manner in which the energy is transferred is still a mystery, although infrared radiation has been suggested (14, 17, 18). In support of the latter contention it has been pointed out that water vapor has several conveniently located bands in its spectrum by which this radiated energy might be absorbed.

The expansion of steam through a De Laval nozzle apparently occurs in the following manner. Up to and slightly beyond the throat, the steam expands in the same fashion as in the super-

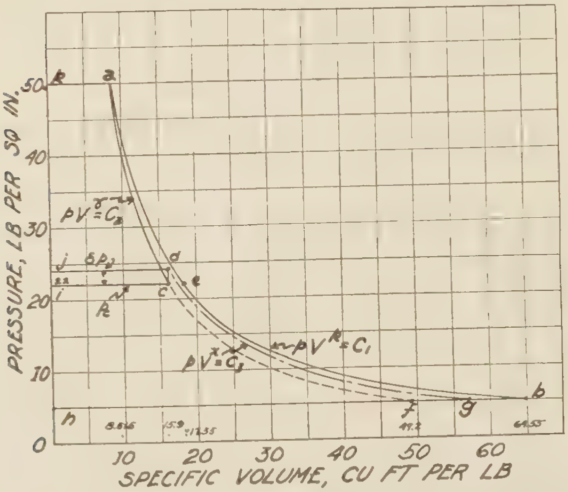

FIG. 13 EXPANSION CURVES FOR WET AND SUPERSATURATED STEAM
(For wet steam $pV^k = C_1$. For supersaturated steam $pV^\gamma = C_2$. For expansion curve d-g, $pV^x = C_3$. Pressure rise $= \delta p$.)

heated region, according to the relation $pV^\gamma = C_1$. The isentropic exponent γ varies with temperature and pressure (16, p. 82), but a value of 1.315 is reasonable for the range in which we are interested. During the expansion, the vapor becomes undercooled with respect to the saturation temperature, and the specific volume is lower than that of wet steam at the same pressure. The expansion follows the line a-c in Fig. 13, while the conventional wet-steam expansion is shown by the line ae. The area between these lines shows the loss which has been caused by supersaturation. A method of evaluating this loss is given in the following section.

When the supersaturation has become sufficiently great, condensation occurs suddenly in the form of a vast number of extremely minute droplets. The latent heat released by the condensed moisture must then be transmitted in some manner to the surrounding vapor, the temperature of which increases. The vapor should expand, but in order to obey the requirements of the continuity equation the velocity would have to increase proportionally. On the contrary, at the condensation point the pressure is observed to rise, which probably means that the process is one of constant volume.

Keenan (13) has shown that this rise of pressure at the condensation point may mean that the drops which actually form are about 5×10^{-9} ft in radius, instead of 1.5×10^{-9} ft as Equation [2] indicates. A similar result can be obtained with the latter drop size, however, if it be assumed that the rise in pressure is just sufficient to maintain constant volume in spite of the increase in temperature which must occur in the vapor.

It has been customary to assume that as soon as condensation occurs, the vapor regains the conventional wet-steam temperature and specific volume (6). The process was considered to be one of constant enthalpy, as shown by the line c-e in Fig 9*a*. Instead, the process is probably one of constant volume, c-d. In addition, the drops which form are so small that the vapor around them must be still undercooled, although to a lesser degree than was the case before condensation. Thus, the temperature at the point d in Fig. 9*b* is lower than the equilibrium temperature at e.

Further expansion probably proceeds from the point d according to the law $pV^x = C_3$ with x having some value between 1.315, for supersaturated steam, and 1.135 for wet steam. For a rough estimate, x may be taken as 1.2.

Analysis of the Effect of Supersaturation. The effect of supersaturation on the flow of steam through nozzles can be treated in the following manner. It has been shown experimentally that, in a rapidly expanding stream, condensation will occur at approximately the same pressure for all initial conditions on the same entropy line. For this reason the following treatment will deal only with expansion from initially saturated conditions. Steam which is initially superheated will behave in the same manner, but it is more difficult to derive general expressions for the losses.

For expansions down to but not below p_c, the following analysis can be made. From the general energy equation for steady flow in an isentropic expansion comes the following basic relation

$$\frac{v_1^2}{2g\,778} + h_1 = \frac{v_2^2}{2g\,778} + h_2 \qquad [4]$$

or

$$v_2^2 - v_1^2 = 50{,}000 \times \Delta h_i$$

where Δh_i is the isentropic change in enthalpy between conditions 1 and 2. Combining the continuity equation

$$w = \text{lb per sec} = \frac{A_1 v_1}{V_1} = \frac{A_2 v_2}{V_2} \qquad [5]$$

with the gas relation for isentropic expansion

$$p_1 V_1^\gamma = p_2 V_2^\gamma \qquad [6]$$

we obtain the relation

$$v_2^2(1 - m^2\beta^{2/\gamma}) = 223.7\sqrt{(\Delta h_i)} \qquad [7]$$

where m is the area ratio A_2/A_1, and β is the pressure ratio p_2/p_1. Since the expansion is assumed to be isentropic

$$\Delta h_i = \int_1^2 V dP = \frac{144\,\gamma}{778\,\gamma - 1}\, p_1 V_1 \left(1 - \beta^{\frac{\gamma - 1}{\gamma}}\right) \qquad [8]$$

Thus the velocity after the expansion becomes

$$v_2 = \sqrt{\left[2g\,\frac{\gamma}{\gamma-1}\,144\,p_1V_1\left(\frac{1-\beta^{\frac{\gamma-1}{\gamma}}}{1-m^2\beta^{2/\gamma}}\right)\right]} \quad\ldots\ldots\ [9]$$

By combining Equations [5] and [9], we obtain the general equation for the flow of a compressible fluid in lb per sec through a nozzle with throat area A_2 sq ft, or

$$w = A_2\sqrt{\left[2g\,\frac{\gamma}{\gamma-1}\,144\,\frac{p_1}{V_1}\left(\frac{\beta^{2/\gamma}-\beta^{\frac{\gamma+1}{\gamma}}}{1-m^2\beta^{2/\gamma}}\right)\right]} \quad\ldots\ [10]$$

Usually we may neglect the term $1/\sqrt{(1-m^2\beta^{2/\gamma})}$, which corrects for the velocity of approach.

For initial pressures up to about 300 lb per sq in. abs, the condensation pressure is always below the critical-pressure ratio, $\beta = 0.55$. Thus, supersaturation will always prevail at least to the throat of nozzles with these initial pressures and the flow

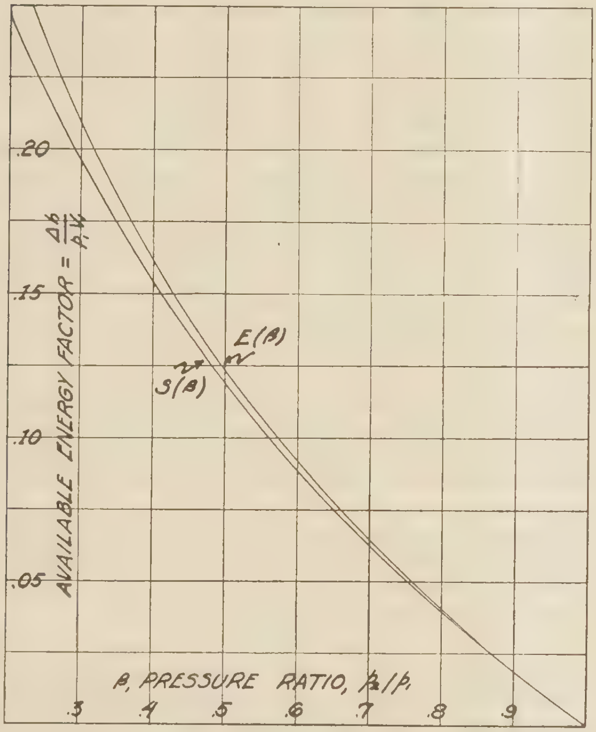

Fig. 14 Available Energy Factors as Functions of the Pressure Ratio p_2/p_1

$\Delta h_e = E(\beta)p_1V_1$ with $k = 1.135$. $\Delta h_s = S(\beta)p_1V_1$ with $\gamma = 1.315$.

$$E(\beta) = \frac{144}{778}\,\frac{k}{k-1}\left[1-\beta^{\frac{k-1}{k}}\right]$$

$$S(\beta) = \frac{144}{778}\,\frac{\gamma}{\gamma-1}\left[1-\beta^{\frac{\gamma-1}{\gamma}}\right]$$

should be calculated by using the superheat value of γ in Equation [10]. For example, assume that saturated steam at 50 lb per sq in. abs is flowing through a nozzle of 1 sq in. throat area against a back pressure of 30 lb per sq in. abs. The flow will be about 2760 lb per hr, whereas the calculated flow, using k for wet steam instead of γ as the exponent in Equation [10], would be about 2590 lb per hr. Thus, the flow coefficient would be about 1.068. Such anomalous flow coefficients have frequently been observed with wet or slightly superheated steam, and they were the principal reason for much of the work which has been done on the subject of supersaturation.

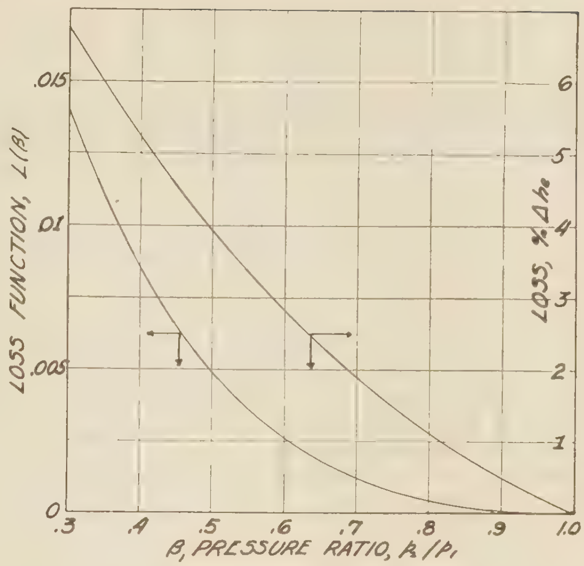

Fig. 15 Values of Loss Function $L(\beta)$ and Percentage Loss Δh_e
(Per cent loss $= (\delta h/\Delta h_e)100$, where $\delta h = p_1V\,L(\beta)$.)

In general, the purpose of a nozzle is to convert into kinetic form the energy made available by the expansion of a gas. The available energy is the isentropic enthalpy change from the initial to the final conditions, for which a general expression appears in Equation [8]. It can readily be seen that the energy available in an expansion from an initial condition p_1, V_1 is a function of the pressure ratio β and the isentropic exponent. Thus, it is possible to write

$$\Delta h_i = p_1V_1 f(\beta) \quad\ldots\ldots\ldots\ldots\ldots\ [11]$$

where

$$f(\beta) = \frac{144}{778}\,\frac{\gamma}{\gamma-1}\left(1-\beta^{\frac{\gamma-1}{\gamma}}\right)$$

By using the proper value of the exponent γ in Equation [8], we may obtain the available energy for either a supersaturated expansion or a conventional wet-steam expansion. Thus, the energy available in an expansion from p_1, V_1 in which the steam is assumed to be in equilibrium with large drops of water can be calculated by replacing γ with the wet-steam exponent k. The value of k varies with the entropy of the expansion, but an average value is 1.135. Denoting by Δh_e the heat available in such an expansion, we have

$$\Delta h_e = p_1V_1\,E(\beta) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ [12]$$

and

$$E(\beta) = 1.555\,(1-\beta^{0.119}) \quad\ldots\ldots\ldots\ldots\ [13]$$

The energy available in a completely supersaturated expansion from the same initial conditions p_1, V_1, can be expressed in the same manner, or

$$\Delta h_s = p_1V_1\,S(\beta) \quad\ldots\ldots\ldots\ldots\ldots\ldots\ [14]$$

Using the value 1.315 for γ in Equation [11], we have

$$S(\beta) = 0.772\,(1-\beta^{0.2395}) \quad\ldots\ldots\ldots\ldots\ [15]$$

These two functions are plotted against β in Fig. 14.

The loss due to supersaturation is represented by the difference between Δh_e and Δh_s. Graphically it is shown by the area between the two expansion curves on the pV-diagram in Fig. 13. Denoting the loss in Btu per pound by δh, we have,

$$\delta h = \Delta h_e - \Delta h_s = p_1V_1\{E(\beta)-S(\beta)\} \quad\ldots\ldots\ldots\ [16]$$

Combining Equations [13] and [15], we have

$$\delta h/p_1V_1 = L = L(\beta) = 0.783 - 1.555\ \beta^{0.119} - 0.772\ \beta^{0.2395} \quad \text{..[17]}$$

Values of the loss function $L\ (\beta)$ can be taken from Fig. 15.

For design work, the loss expressed as percentage of Δh_s is of importance, since Δh_s can be read directly from the Mollier diagram. The loss δh expressed in per cent is

$$\text{per cent } \delta h = \frac{\delta h}{\Delta h_s} \times 100 = \left(1 - \left[\frac{\Delta h_s}{\Delta h_s}\right]\right) \times 100 = \left(1 - \left[\frac{E(\beta)}{S(\beta)}\right]\right) \times 100 \quad \text{..........[18]}$$

Per cent δh is plotted against β in Fig. 15.

Since the product p_1V_1 varies with the initial conditions, the actual loss δh, in Btu per pound, also varies; Fig. 16 shows the losses for initial conditions of 10, 50, and 100 lb per sq in. abs, saturated. Since the loss functions discussed previously are not valid beyond the condensation point, each of the lines on Fig. 16 stops at its particular condensation pressure. It will be noticed that the supersaturation loss is decreased as the initial pressure is raised. This is to be expected, for if the pressure is raised to the critical point, there will be no supersaturation and hence no loss.

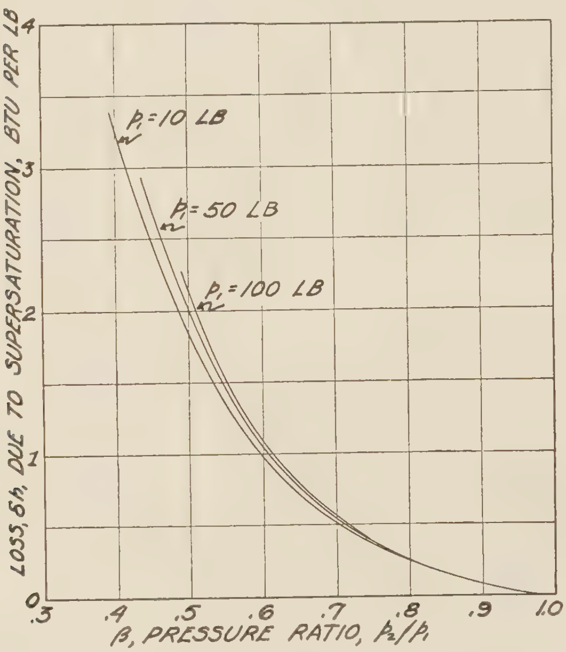

Fig. 16 Loss Due to Complete Supersaturation; Values Not Valid Beyond Condensation Pressure

By referring to the pV diagram in Fig. 13, it can be seen that when an expansion proceeds beyond the condensation pressure p_c there is a sharp recompression to d, probably at constant volume. This recompression causes a momentary decrease in the kinetic energy, but this decrease is regained as soon as the expansion again passes p_c. The total loss due to supersaturation for expansions beyond the condensation pressure is made up of the loss δh discussed previously, plus a secondary loss caused by the partially supersaturated expansion from d. The droplets which form at c are so small that undercooling must still exist as the expansion proceeds. Evaluation of this secondary loss is not yet possible because the magnitude of the pressure rise from p_c to p_d must be studied in more detail. Likewise, the exponent x for the expansion beyond d is not known. An additional factor which must be considered is the acceleration of the water droplets by the steam.

An estimate of the total losses of energy which occur in the expansion of saturated steam can be made from the results of several tests reported by Stodola (6, p. 1054). In the first case, steam expanding from 116 lb per sq in. abs and 7 F superheat, to a back pressure of 15.4 lb per sq in. abs, gave a reaction of 23.92 lb with a flow of 0.298 lb per sec. The velocity coefficient was 0.95 and the nozzle efficiency was 90 per cent. In the second case, the initial conditions were 158.7 lb per sq in. abs and 15 F superheat; the back pressure was 8.13 lb per sq in. abs; and the reaction was 38.80 lb with a flow of 0.399 lb per sec. The velocity coefficient for this case was 0.94 and the nozzle efficiency was 88.5 per cent.

Summary of Results

As a primary result of this work, it may be said that the Wilson line for continuously expanding steam in De Laval nozzles is located at about the 4.5 per cent moisture line on the Mollier diagram. The droplets which form there are small compared to the wave length of blue light and they do not grow in the nozzle unless the angle of divergence is less than 2 deg.

Initially saturated steam can in several ways be made to condense at about the 2 per cent moisture condition, which thus becomes the upper limit of the Wilson zone. This type of condensation can be brought about by making the angle of divergence less than 2 deg or by raising the back pressure to within a few pounds of the initial pressure. Under these conditions, the drops grow rapidly and usually achieve a size of the order of magnitude of red light waves as they leave the nozzle.

Steam which is initially superheated can be made to produce preliminary condensation only if the throat of the nozzle is very long.

It is estimated that the order of magnitude of the radius of the droplets formed in ultimate condensation is about 1.5×10^{-9} ft. This value was obtained by applying the Kelvin law, the accuracy of which is very doubtful, but the optical evidence gives support to it.

The losses caused by supersaturation can be evaluated accurately for expansions which do not reach the condensation point. For expansions which go beyond this point the losses can be approximated.

Acknowledgments

Although the number of those who have rendered assistance in various stages of the work is so great that individual mention cannot be made, the authors wish especially to acknowledge their indebtedness to Prof. J. W. Gavett of the University of Rochester and to the staff of the department of mechanical engineering of Stevens Institute. Financial assistance from The American Society of Mechanical Engineers is gratefully acknowledged, and the authors wish to express their gratitude to Geo. A. Orrok and C. B. Le Page. The actual construction of the apparatus was done by Carl Oelkrug of Stevens Institute, and his precise workmanship was invaluable.

Production and Quality Control of Sheets for Automobile-Body Fabrication

By T. F. OLT,[1] MIDDLETOWN, OHIO

Comparisons of the older and newer methods of rolling wide mild-steel drawing sheets are presented in this paper. The aspects of quality control in the modern sheet mill are dealt with, and quantitative data are given covering the effects of variations in the cold-reduction, normalizing, box-annealing, and temper-rolling operations. The data presented are typical rather than exhaustive.

PROGRESS in the sheet-rolling industry has been rather extensive within the last decade, and one of the most interesting phases of this development has been the growing demand for wider and thinner high-finish drawing sheets than were obtainable heretofore. Considering the number of years they have been available, the production of wide high-finish drawing sheets might be said to be in its early stages. Even so recently as eight years ago, a 19-gage sheet measuring 52 × 58 in. was considered to be quite large, and the losses connected with the production of sheets of this size on the prevailing sheet-bar practice were quite high. In those days high-finish sheets were still being rolled from the conventional 8-in. sheet bar, using the practices that had been developed during the past century, plus, of course, the most recent developments such as pickled breakdowns, charcoal dips, and loose rolling. In 1921, The American Rolling Mill Company purchased the Ashland Iron and Mining Company property, which lacked sheet-finishing facilities, and proceeded to install the first commercially successful so-called "continuous-sheet mill." (1)[2] The problems connected with the development of this mill were many and varied, one of the principal difficulties being to secure rolls which would stand up under continuous operation. However, this problem was overcome and the mill was made to produce sheets up to 48 in. wide in 20 gage and heavier with very good surface characteristics and drawing properties.

Previous to 1921, a very good quality of strip was available in widths up to 20 in. which was being produced on continuous cold strip mills. So far as surface and drawing quality were concerned, this product was superior, by a considerable margin, to sheet products available. However, in November, 1926, The Columbia Steel Company, which a few months later became the Butler Division of The American Rolling Mill Company, commenced the rolling of strip sheets (2) in coils in widths up to 36 in., using a combination of hot and cold rolling similar to the practice used in the narrower strip mills, the main difference being in the equipment and mills which handled the strip. The installation at Butler was quickly followed by others at Weirton to hot roll strip up to 48 in. wide, at Trumbull to hot roll strip up to 36 in. wide, at The American Sheet and Tin Plate Company, Gary, Ind., to hot roll strip up to 36 in. wide, and at the Middletown Division of Armco in 1928 to hot roll strip up to 52 in. wide. Fig. 1 is a view of the finishing stands of the Middletown hot-strip mill.

With the construction of the wide hot-strip mill at Middle-

Mr. Olt was graduated from the University of Cincinnati in 1928 with the degree of chemical engineer and since graduation has been associated with The American Rolling Mill Company. Previous to 1934 he was employed in the operating division in various metallurgical capacities. Since 1934 he has been in the research laboratories in charge of the research and development of high-finish drawing sheets and stainless-steel products.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Iron and Steel Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held at Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

town, the sheet mill was rebuilt to use the product of the hot-strip mill as breakdowns for the hot finishing of sheets, using continuous-pack heating furnaces and three-high hot mills (similar to those in successful use at Ashland on narrower widths) for the production of sheets 50 in. and wider. By 1932 the production of thin-gage wide and long sheets had progressed to such a point that sheets 0.037 in. thick and as large as 66 × 120 in. made on hot mills were available to the automotive industry in

quantities large enough for the production of certain items requiring wide high-finish sheets.

During this period, wider and more powerful hot-strip mills were in the process of being built first to roll sheets 60 in. wide, then 72 in. wide, and then 90 in. wide. At present there is a new construction in Cleveland which is reported (3) to have a width limit of 98 in. In 1936, the hot-strip mill at the Middletown Division of Armco was widened (4) to 80 in. to provide wide coils for the cold-strip mill which has recently been constructed there. Fig. 2 is a view showing the Middletown coldstrip mill. Fig. 3 is a diagrammatic representation (5) of the volume and capacity of sheet production in the United States which indicates that the growth of sheet capacity since 1924 has been almost entirely in the continuous-strip process of making sheets. In this same period, cold-rolling mills have been improved continuously with better reels, rolls, bearings, electrical gear, and controls which enable cold reduction to be performed on coils at high speeds under very definitely controlled conditions of screw pressure, thickness, and tension between tandem stands.

Comparison of the Sheet and Strip Practice in the Manufacture of Wide Sheets for Drawing Purposes

There are numerous methods by which a wide cold-rolled sheet of drawing quality may be produced. For purposes of comparison, consider a sheet 0.040 in. thick, 63 in. wide, and 103 in. long, which in the present day is neither unusually wide, long, nor thin. In the first place, the quality and analysis of the steel used is of utmost importance. The quality must always be good and the analysis will depend to a great degree on the methods selected for manufacture of the sheet and the drawing or stamping hazards which the sheet must undergo.[3] Steel used for difficult stampings is usually of the rimming type, with an analysis in the following range: Carbon from 0.04 to 0.10 per cent; manganese from 0.20 to 0.45 per cent; phosphorus below 0.04 per cent; sulphur below 0.05 per cent; and other elements as low as possible.

In the casting of an ingot within the composition given, there is a segregation of some of the elements involved which must be taken into consideration in selecting the method of rolling and processing for the material being produced. Fig. 4 gives an indication of the amount of segregation that is sometimes obtained in casting a rimming steel ingot. It will be seen that there is a segregation of carbon, copper, and sulphur which

[3] The drawing and stamping hazards will vary somewhat between different fabricating plants on the same type of stamping, and for this reason it is necessary to maintain an extremely close contact between the mill and fabricator in order to maintain a steady flow of material suitable for the particular job concerned.

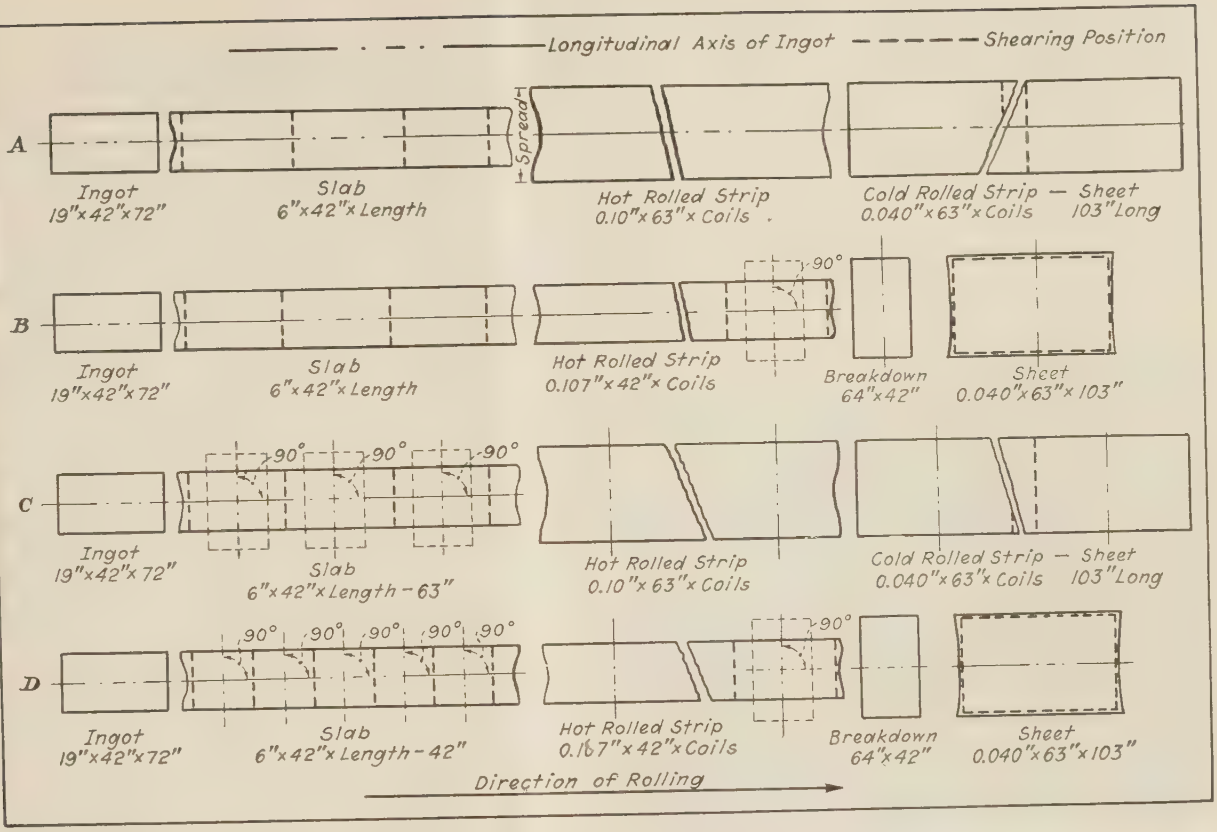

FIG. 5 VARIOUS METHODS OF ROLLING WIDE SHEETS

(*A*, Ingot rolled essentially straight throughout. *B*, Ingot rolled straight to hot strip, hot strip turned and hot rolled to finished gage. *C*, Ingot rolled to slab, and slab then turned and rolled to finished gage. *D*, Ingot rolled to slab, and slab then turned and hot rolled to hot-strip breakdown gage, after which the hot-strip breakdown is again turned and then hot rolled to finished gage.)

are all potent hardeners. In making ingots for deep drawing sheets, special efforts are made to keep the segregation of elements to a minimum.

The four methods by which the sheet we are considering can be rolled to finished gage are shown schematically in Fig. 5.

The first method is used to a very great extent in the narrow-strip mills and many of the wide-strip mills to make sheets up to a width approaching that of the ingot. To make sheets wider than the ingot, this method can be modified by spreading the slab laterally in the first stand of the strip mill to a width suitable to produce the desired width of strip, which very seldom requires a reduction greater than 50 per cent of the original slab thickness. If we start with an ingot 19 in. thick, 42 in. wide, and 72 in. high, and roll to strip having a thickness 0.10 in. and a width of 63 in., the ratio of the strip to ingot will represent an elongation of 126.5 times parallel and 1.50 times transverse to the long dimension of the original ingot. When rolled to the finished gage of 0.040 in., the elongation will be 316 times and the lateral spread 1.50 times from the original ingot. Had the sheet been rolled to a width of 42 in., there would have been no lateral spread except the small amount that always takes place when metal is rolled, and the elongation in this case, considering a final gage of 0.040 in., would have been 475 times.

The second method mentioned is not often used in the manufacture of wide sheets except for some particular reason; however, the practice of making sheets from sheet bar is similar to this process, the difference being in the division of the reduction that is parallel and that which is transverse to the axis of the ingot. In the case of sheet hot rolled from strip breakdowns, the division of elongation is 183 times parallel and 2.59 times transverse to the ingot axis. In the case of this sheet hot rolled from 8-in. sheet bar, which would probably be made from a 19 × 22-in. ingot, the division of elongation is 91.5 times parallel and 5.2 times transverse to the axis of the ingot. The latter is a net figure, since the final rolling from an 8-in. sheet bar is an elongation of 14.2 times while the sheet bar was contracted 2.75 times.

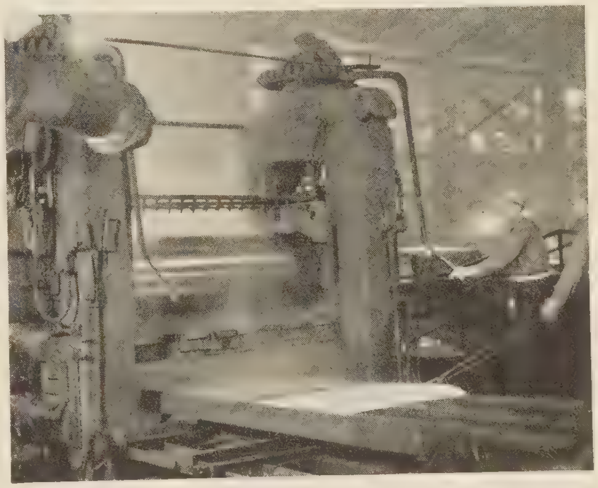

FIG. 6 THREE-HIGH HOT FINISHING MILL

The third method is the one ordinarily used in the Armco Middletown Division in the manufacture of wide sheets by the cold-reduction process. In this case the ingot is slabbed, turned, and hot rolled to strip approximately 0.10 in. thick. The slab length, and hence its thickness, depends upon the desired width of the hot-rolled strip. For instance, if the strip mill is to roll coils 63 in. wide, the length of the slab must be such that they can get three 63-in. cuts and still have enough metal to get the necessary croppage. If they plan to roll a strip 40 in. wide the slab is rolled to a length suitable to get four cuts plus croppage. After rolling on the hot-strip mill, the strip is then pickled and cold rolled to the desired thickness of 0.040 in. The elongation in this case is 3.16 times parallel and 150 times transverse to the ingot axis.

Fig. 7 Two-High Hot Mill

The fourth method mentioned is used at Middletown when hot-strip breakdowns are hot rolled to sheets using the three-high hot mill. Fig. 6 shows a typical three-high mill. The ingot is slabbed to 6 in., reheated, turned and rolled to breakdown thickness, sheared to length equal to the width of the desired sheet plus side scrap, then turned again and rolled to gage. The elongation of the sheet in this case is 8.2 times parallel and 58.0 times transverse to the axis of the ingot.

All of these methods of rolling have certain advantages and disadvantages. The first two methods allow the production of longer and heavier units of semifinished product such as hot-rolled coils with a somewhat greater yield from the ingot. In cross-rolling slabs, the weight of the coil is limited by the slab thickness the first stand in the bar mill will take, and also the maximum reductions that can be taken in producing the desired thickness in the hot-rolled coil with the mills available, together with the maximum ingot width that can be handled in the slabbing mill. In addition, it is necessary to roll the slabs very closely to the desired slab length in order to secure the proper yield from the ingots, since the losses mount rapidly if the slabs are rolled with too much croppage on either end. On the other hand, if the slab be too short, an entire cut is lost which may amount to as much as, or more than, one third of the ingot. The greatest advantage in cross-rolling is that the resultant sheets are more uniform within the single sheets in so far as segregation effects are concerned. Sheets produced by this method do not have a soft edge and hard center from the more segregated portion of the ingots, which is the case when the material is rolled straight essentially throughout the whole reduction. The magnitude of this difference in properties is shown in Table 1.

This is a very important consideration in drawing sheets for some requirements, since a variation in physical properties between the edges and the center of sheets will sometimes cause a lack of uniformity in the manner in which the metal flows in the drawing dies. When the complete product of any one ingot is concerned, however, the whole range in physical properties is secured by either practice; in fact, in cross-rolling slabs, the major portion of scrap which is subsequently lost (coil crops) represents some of the least segregated metal of the original ingot.

As pointed out, a sheet 0.040 in. thick, 63 in. wide, and 103 in. long can be made either by hot reduction or cold reduction from hot-rolled strip approximately 0.10 in. thick. The most modern method is to reduce to the finished sheet gage cold rather than hot. The most important reasons for the selection of the cold-reduction process are economy, improved quality, decreased losses, and flexibility.

In the older hot-rolling process for manufacturing wide sheets, the customary procedure is as follows: (*a*) Pickle hot-rolled strip in cut lengths; (*b*) heat and breakdown to 80 per cent finished sheet length; (*c*) pickle breakdown; (*d*) reheat breakdowns and roll to length; (*e*) mill shear; (*f*) cold roll to flatten and even thickness; (*g*) normalize; (*h*) pickle; (*i*) bright anneal; (*j*) temper pass and roller level; and (*k*) inspect.

The oldest method of hot rolling sheets from sheet bar is similar to the foregoing practice except that more heatings and breakdowns are required in the sheet mill. Fig. 7 is typical of the old style two-high hot mill for sheet bars.

As a comparison, the customary sequence of operations in the manufacture of wide sheets by the most modern cold-reduction method consists of: (*a*) Pickle hot-rolled strip in coils; (*b*) cold roll to gage; (*c*) shear to length; (*d*) bright anneal; (*e*) temper pass and roller level; and (*f*) inspect.

A comparison of these two general practices will indicate that the old hot-rolling method requires five more separate operations than the modern cold-reduction method, and being performed in unit sizes entails the production of a great deal more scrap than is produced by the cold method. In addition, there are always a great many more rolling rejections such as pinchers, jumpers, and floppers produced in hot rolling than in the most modern methods of cold reduction where the rolling is performed with very rigid mills equipped with tension coilers and also tension

between the tandem stands. Another outstanding advantage of the cold-reduction process is in the improvement of the sheet surface both from the standpoint of freedom from defects as well uniformity of appearance.

The differences between the old and new methods of manufacturing wide sheets have been indicated in the foregoing tabulations of the sequence of operations and will be considered at greater length and in more detail in the next paragraphs. It is largely due to the rolling methods, however, that it has been possible to decrease the costs and increase the yield of prime high-finish sheets so that the sheet manufacturers have been able to reduce the cost to the consumer as is shown in Table 2.

The net price in 1936 is the same as the price in 1932 despite the fact that labor and raw-materials costs have been increased materially. In this discussion, it has been presumed that the cost of production and selling price are interrelated, which is usually the case in a highly competitive market such as the sheet market.

By decreasing the selling price of wide drawing sheets, the fabricator has been enabled to make single stampings, formerly made in multiple parts and assembled, at decreased costs which has resulted in greater sales, and hence, greater demand on the sheet producer. This expanded demand for sheets has further reduced costs of manufacture with resultant savings to the sheet consumer.

It will be apparent from the foregoing, that for two hundred years the art of rolling sheets had not changed in method and but little in practice. However, after the first successful continuous mill was operated by The American Rolling Mill Company at Ashland, Kentucky, in 1924, the flat-rolled-steel industry spent in the neighborhood of $300,000,000 for new rolling equipment which provided material in sizes and tonnages not previously considered possible. At the same time it has made an improved quality of material available for the automobile industry at a reduction in cost of approximately 50 per cent.

Quality Control in the Modern Sheet Mill

There are numerous factors which must be considered in order to produce a satisfactory sheet for some particularly difficult drawing requirement. As stated previously, by far the most important consideration is to have a satisfactory base material from which to start.

There has been a constant drive in the open-hearth to make lower-carbon rimming-steel ingots to almost a spot specification, taking particular care to see that there is a minimum of alloy contamination. This job has been made constantly more difficult due to the scarcity of the most desirable raw materials. The available pig iron or hot metal contains more copper, if the blast furnace is being scrapped to increase the output, and the scrap commercially available is constantly being contaminated with alloying elements such as copper, nickel, and chromium, being generated in this age of alloy steels. While alloy scrap is usually sold separately from the regular run of No. 1 and No. 2 scrap because of its higher value, it is mixing in with the open-hearth scrap to an ever increasing extent. In order that the proper analysis be obtained in the ingot, it is often necessary that scrap be selected and the charge melted in such a manner that the sulphur content be low. Metallurgical observers stationed in the open hearth are constantly on the job to make certain that all vital operations are carried out according to prearranged plans, that the heat has the proper temperature when tapped and poured, and that the steel has the proper rimming action in the molds.

After the ingots are stripped (and care is taken to see that they are not stripped too soon), the ingots are charged into the soaking pits and carefully heated for rolling. Temperatures are regularly checked in the pits, at the slabbing mill, at the slab shears, and between certain stands in the bar and hot-strip mill by recording radiation pyrometers in order to maintain uniformity of rolling conditions and grain structure. Fig. 8 shows such an instrument installed. Cooling water is used copiously to insure that the strip is not reeled into coils at temperatures sufficiently high to cause critical grain growth. The strip mill has numerous banks of high-pressure hydraulic sprays which are used to descale the strip. It is vitally important that the surface of the hot-rolled strip be free from scale matte or rolled-in scale if the finished sheet is to be satisfactory for fabrication into many products requiring a smooth surface. A careful watch must be maintained on the surface of the rolls in all of the stands in the strip mill, watching particularly for spawls, fire cracks, and pickup

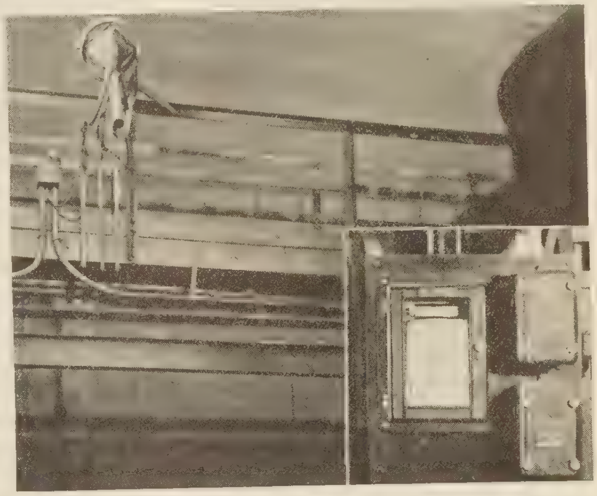

Fig. 8 Radiation Pyrometer and Continuous Recorder at the Finishing Stand in the Hot-Strip Mill

the results of which often do not show up until the sheets are being drawn in the fabricator's plant where the roll defects show up as slivers and fins. The open-hearth metallurgist maintains complete records of the melting and rolling characteristics of the various heats which go into the same item, and charts the trends of any variations in practice. On particularly difficult jobs it is sometimes desirable to remove some of the more highly segregated portion of the ingot for reapplication on an item where the physical requirements are not so stringent.

In the cold reduction of the hot-rolled strip to gage, the sheet producer has another opportunity to tailor his product. He may vary the amount of cold reduction necessary to reduce the hot strip to the desired thickness within the limits of the capacities of the hot-strip mill and the cold-strip mill, to produce a sheet having the physical properties that he desires. Hayes and Burns (6) have shown the variation in grain sizes that can be produced with different amounts of cold reduction up to 60 per cent, and also the variation in size after annealing at 1100 and 1350 F, which have been reproduced in Figs. 9, 10, and 11. In general, a cold reduction of at least 30 per cent is necessary if the next operation is to be a box anneal at 1200 F or higher in order to avoid the production of extremely coarse-grained material that is unsuited to any forming and drawing requirements. The effect of variations in the amount of cold reduction on the physical properties for annealing temperatures of 1100 and 1350 F is shown in Fig. 12. The sharp breaks exhibited in the curves between 5 and 20 per cent cold reduction are due to an uneven coarse grain caused by a critical degree of strain (7) before box annealing.

(Original magnification of ×100 has been reduced 50 per cent.)

In selecting the amount of cold reduction to be used, the sheet-mill metallurgist is governed by a number of factors, among which are: (a) The severity of the drawing operation; (b) the surface requirements, both in the severely strained and undisturbed areas of the stamping; (c) the analysis of the steel to be used; (d) the annealing cycle to be used; and (e) the mechanical limitations of the hot- and cold-strip mills. Usually the figure arrived at by weighing all of the different factors is somewhere between 30 and 70 per cent.

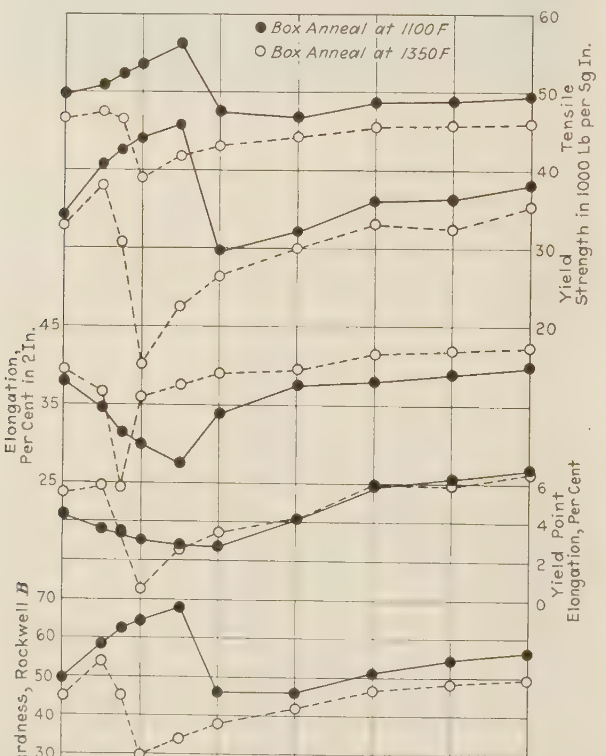

Fig. 12 Physical Properties of Mild Steel Cold Reduced Various Amounts and Box Annealed at 1100 and 1350 F

In the most modern methods of processing, sheets which have been cold reduced in excess of 30 per cent are usually annealed in a stationary box-type of in-and-out furnace in heavy packs, or if the newest development of box-annealing equipment is used, it would more properly be termed a box-type on-and-off furnace. The newest construction of box-annealing furnaces utilizes a number of bases on which the charge is built. After covering the charge in a suitable manner, the heating unit is lowered over the covered charge and fired until the heating and soaking cycle has been completed. Then it is lifted off and removed to the next charge to be annealed. For very wide and long sheets, the charge may be as much as 50 to 75 tons. The annealing is carried out under closely controlled conditions, usually automatic, and with elaborate precautions to see that no part of the charge is overheated while the coldest part is coming up to temperature. A protective gas atmosphere is added under the cover to prevent the sheets from scaling during the cooling cycle. The temperatures ordinarily used are from 1250 to 1350 F, depending on the fabrication to be performed, the steel that is being used, and the efficiency of the separating medium on the sheets to keep them from welding together at the annealing temperature. Fig. 13 shows a charge of sheets with thermocouples placed before covering. Fig. 14 shows the automatic control system that is used to insure the proper rate of heating and time of soaking to produce a thorough and uniform annealing of the charge.

In the older process of hot rolling to finished gage, the sheets were invariably normalized to recrystallize and refine the grain structure, thus erasing the variations from the hot-mill rolling. If these sheets were to be box annealed as the cold-reduced sheets are, the grain size would be extremely nonuniform and the physical properties very poor since the amount of strain

remaining in the sheets after the hot-rolling operation is in the critical-strain (7) range for low-carbon rimming steel. The hot-rolling operation in wide sheets is not nearly so susceptible to close control as it is on narrower sheets in so far as residual strain in the sheet is concerned. This is because on wide sheets the hot-mill roller must be allowed sufficient latitude in his heating temperatures so that he can coordinate the shape of his mill, the drafts he must take, the shape of his breakdowns and other factors, in order that he can produce a sheet of sufficient length to shear out and be free from surface defects such as pinchers, jumpers, and scale matte. The magnitude of these variables is decreased considerably in rolling narrow sheets, and conditions can be controlled to such an extent that these sheets can be box annealed without encountering critical grain growth. The manufacturer who hot rolls wide light-gage sheets has at best a most difficult task to produce the required tonnage with nominal scrap even when taking full advantage of the latest mechanical developments in hot-mill heating and rolling equipment.

In the normalizing operation, the sheet producer has another opportunity to tailor his product according to the customer's demands. He has the opportunity to vary his normalizing temperatures and heating and cooling rates. The effects of such variation on grain size are shown in Fig. 15. In general, the slower the cooling rate, the larger the resulting grain size will be. While most of the product that is normalized is rolled on a hot mill, cold-reduced sheets may be normalized when it is so desired (and such is often the case, even with the additional expense involved). Cold-reduced sheets which have been normalized are in general slightly finer grained and harder than the hot-rolled product, when the normalizing cycle is the same. A comparison of the hardness of hot-reduced and cold-reduced normalized sheets is shown in Fig. 16. These data have been plotted in the form of curves showing the cumulative percentage of tests below any given hardness within the range of tests. The width of the range is in a large part due to segregation effects in the ingot. The metallurgical department patrols this operation very closely, making a great number of tests from which distribution curves are drawn for varying furnace practices and analyses. The control is then worked on a method of extremes and averages, inasmuch as the range of hardness is somewhat wide on any one

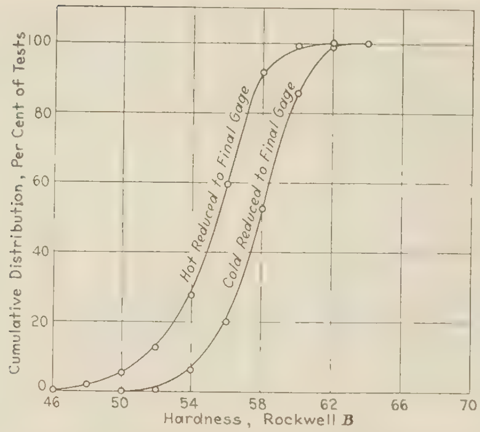

FIG. 16 EFFECT OF METHOD OF ROLLING ON ROCKWELL HARDNESS AFTER NORMALIZING

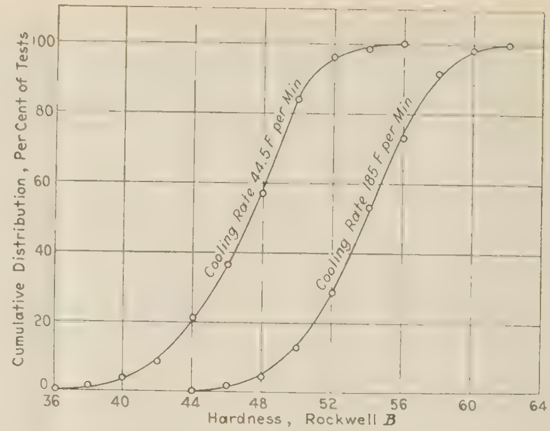

FIG. 17 EFFECT OF RATE OF COOLING FROM NORMALIZING TEMPERATURE ON THE ROCKWELL HARDNESS OF MILD-STEEL SHEETS

heat due to the segregation effects in the ingot. Another such curve is shown in Fig.17 which shows the effect of a variation in cooling rate on the cumulative distribution of Rockwell-hardness values.

After the normalizing operation, the sheets are pickled to remove scale, temper rolled a specified amount on smooth rolls to improve the surface and flatness, and then reannealed to remove the cooling strains from normalizing and also the strains from the temper rolling. This annealing is carried out in box-type in-and-out furnaces similar to those referred to in the anneal-

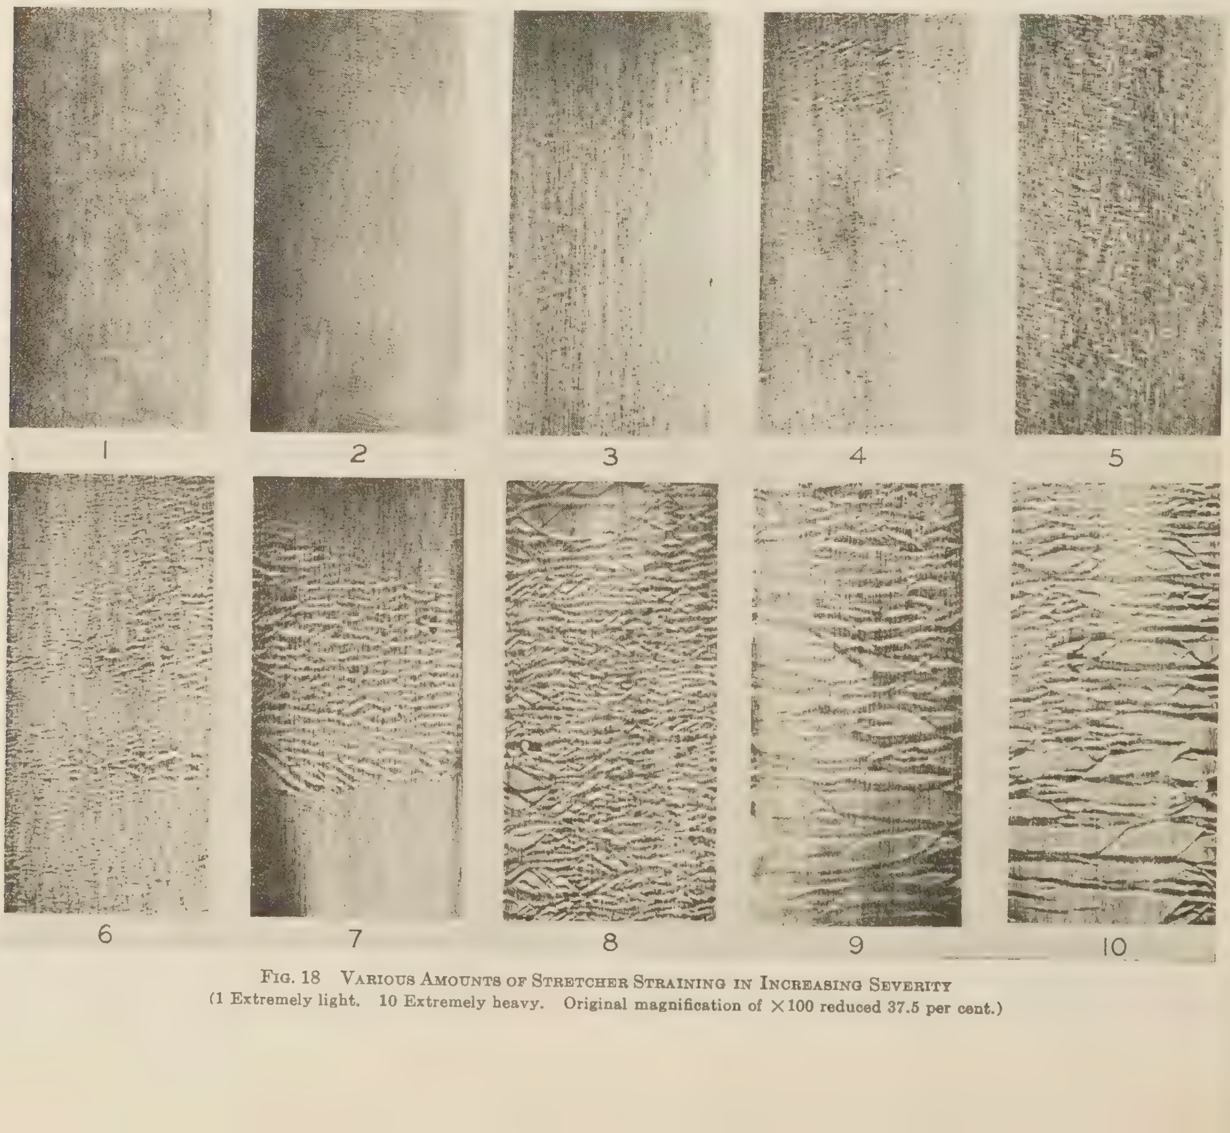

FIG. 18 VARIOUS AMOUNTS OF STRETCHER STRAINING IN INCREASING SEVERITY
(1 Extremely light. 10 Extremely heavy. Original magnification of $\times 100$ reduced 37.5 per cent.)

ing of cold-reduced material, and the same precautions are taken in heating the charge. The annealing temperature used to relieve the strains varies from 950 to 1200 F, depending on the requirements of the customer's fabrication.

After the sheets from either process have been box annealed, they are ready for temper rolling or the pinch-pass operation where the metallurgist has his final opportunity to control the results that will be had in the drawing operation. Sheets have their maximum ductility and minimum hardness after annealing, and it is extremely unfortunate that they cannot be drawn in this condition without objectionable surface disturbances taking place. These surface disturbances are known as "stretcher strains," "worms," or "Luders lines" and are intimately connected with the elongation that takes place at the yield point when a tensile sample is stretched. Fig. 18 shows the appearance of these stretcher strains. The yield-point elongation of well-made sheets or strip in the annealed condition is usually within the range of 3 to 7 per cent and can be completely removed by temper rolling (pinch passing); and when completely removed, the material no longer shows these characteristic surface disturbances. This subject has been covered intensively in a number of papers (8, 9, 10) and will only be considered briefly here. Two of the factors with which the yield-point elongation of annealed mild-steel sheets is related are:

1 Ratio of the yield point to tensile strength (often termed "elastic ratio"): The lower the elastic ratio, the lower the yield-point elongation.

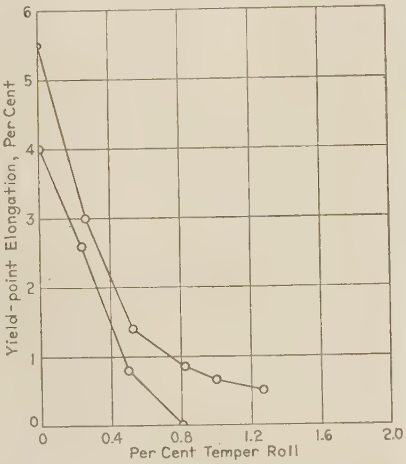

Fig. 19 Effect of the Amount of Yield-Point Elongation as Annealed on the Amount of Temper Rolling Necessary to Eliminate the Yield-Point Elongation. Temper Rolling Done With 4-In. Diameter Rolls

2 Grain size: Generally, the finer the grain size, the greater the yield-point elongation.

The amount of temper rolling necessary to remove the yield-point elongation completely is directly proportional to the yield-point elongation of the annealed material (6). This relationship is shown in Fig. 19.

Unfortunately, temper rolling, while eliminating the yield-point elongation and also the corresponding tendency to stretcher strain when performed in increasing amounts, also increases the

hardness and decreases the ductility. Still more serious, it sets off the aging tendency (10) which further deteriorates the physical properties with time. Under these conditions, it is customary in the mill to temper roll an amount slightly greater than the minimum amount necessary to prevent the sheets from stretcher straining when used within a reasonable period of time and not so much as would cause an extensive increase in breakage in the drawing operation.

The amount of temper is customarily specified as a certain percentage of elongation of the annealed sheet. Charts, an example of which is shown in Fig. 20, have been prepared from which the temper roll operator can rapidly determine the actual elongation in fractions of an inch to be applied to the sheet. The percentage temper rolling will usually be in the order of from 0.3 to 3 per cent. Measurements are taken throughout the lift of iron being rolled by temper-roll checkers attached to the metallurgist's staff to insure the proper temper being applied. On wide sheets it is customary to measure the elongation on both sides and also in the middle to be sure that the mill is pulling straight, since a variation in pull of as much as 1 per cent between the two sides of a sheet 63 in. wide will not be apparent as readily in the form of camber as it would be on a sheet only 30 in. in width. With close control it is possible to temper roll wide sheets as close as plus or minus 0.1 per cent of the specified amount.

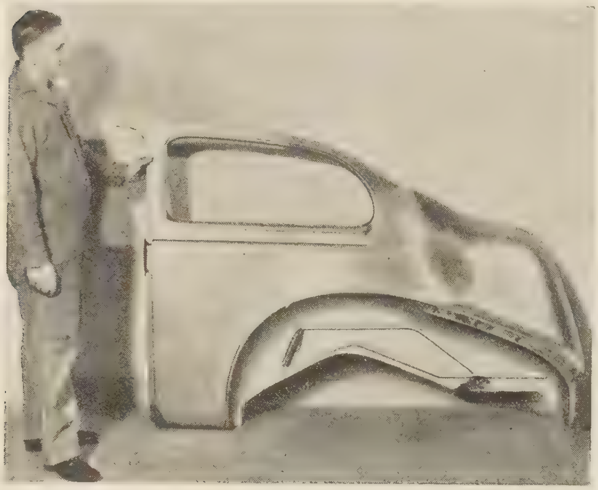

Fig. 22 A Finished Quarter-Panel Ready for Application to an Automobile Body—Archer and Geuder (11)

After temper rolling has been completed, the sheets are inspected, packed, and shipped. If the fabricator uses the sheets promptly after their arrival, a minimum of difficulty can be expected in so far as changes due to aging are concerned. The magnitude of the deterioration in physical properties experienced with time (aging) on tempered drawing sheets is given in Table 3 and the trend is shown in Fig. 21. In addition to the hardening action and loss of ductility, the yield-point elongation also comes back with the resultant difficulties associated with surface disturbances such as stretcher strains.

We have dealt with the manufacture of wide sheets by several different processes, of which the essential difference, in so far as metallurgical characteristics are concerned, is in the manner in which the sheets have been reduced to gage and then annealed. Aside from economy and improved surface, the most modern practice of cold reduction to gage followed by annealing has another great advantage over the older processes requiring both normalizing and annealing. This advantage is in the improved physical properties that are obtained by the most modern method. A typical comparison of these differences may be observed by referring to Table 3.

It will be noted that the yield strength, tensile strength, and hardness of the cold-reduced annealed sheet are lower and the percentage of elongation in 2 in. has been increased to the extent of approximately 2.5 per cent. In addition, the metal has less tendency to buckle in the dies and to spring back when removed from the dies due to the initially lower yield point which allows flow into the dies at lower unit stresses than with initially harder and tougher material. The principal disadvantage with cold-reduced annealed sheets is their increased tendency to stretcher strain after short periods of aging as compared to a normalized box-annealed sheet.

Application of Wide Sheets in the Automobile Body

The developments in the utilization of wide cold-rolled drawing sheets in automobile-body and fender fabrication have been published by Winlock and Kelley (9), Archer and Geuder (11), and Beaudoin (12). From 1928 to the present time it has been the problem of the steel mills to give to the automotive industry all of the wide sheets that they required. It was formerly the practice to make the rear quarter of an automobile body in a

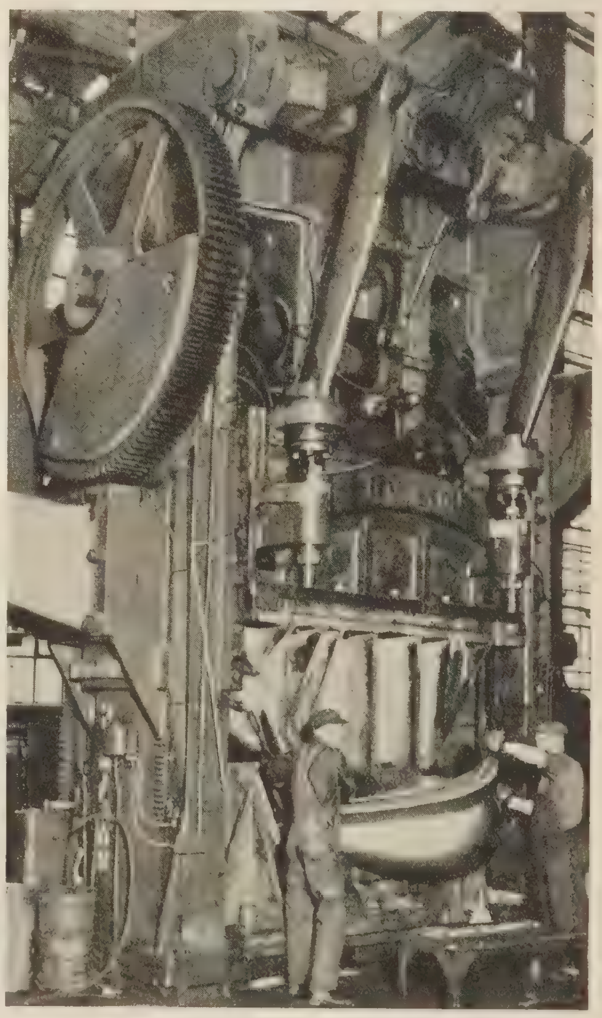

Fig. 23 Drawing a Buick Front Fender—Beaudoin (12)

number of stampings, such as the upper quarter-panel, the lower quarter-panel, the wheelhouse panel, and roof rail, which were fastened together in various manners, most often by welding, and the joints covered with decorative trim. Present practice is to use wide sheets and eliminate as many welds and operations as possible as is evidenced by the single stamping now being used for a rear quarter-panel, an example of which is shown in Fig. 22. In some plants a complete side panel for the body is made in one stamping.

Fenders which were formerly made with a crown and apron, are now being made in one piece as shown in Fig. 23, which also includes the hood ledge. Another notable new use of wide sheets is in the one-piece drawn-steel top, shown in Fig. 24, which was pioneered by Fisher and is now practically standard equipment on closed cars throughout the automotive industry. Not many

Fig. 24 Turret Automobile Top Ready to Be Welded to a Complete Body. There Are Only Four Points at Which This Top Is Welded to Additional Panels—Archer and Geuder (11)

years ago such a stamping would have been impossible both from a sheet and press standpoint unless it had been assembled from a number of smaller stampings.

Another present-day trend in the automobile-body-fabricating industry is toward the use of "sheets in coils," or wide-strip coils, in order to blank irregular shapes with greater economy, in so far as scrap is concerned, than would be possible from rectangular sheets. Parts being made from wide coils now include side panels, radiator shells, front and rear fenders, hood tops, hood sides, and running boards.

As is usual in cases where rapid progress has been made, the art in many cases has preceded the science, and were it not for the wholehearted cooperation of the body fabricators and stamping shops, it is quite doubtful whether the development of wide drawing sheets would be as far along as it is at the present time. The installation of processing levelers of the Budd-McKay type has been very helpful in the utilization of sheets having a tendency to stretcher strain, which might have been due to slightly undertempering at the mill or to the effects of aging.

It is general sheet-mill practice to have mill representatives and metallurgists frequently contact the sheet-consuming industries so that any slight adjustments that are required in the sheet-production methods can be made as the need arises. This enables the mill to clearly understand the customers' requirements and make changes in processing of material to meet specific requirements. In most cases the cooperation between the consumer and the mill has been so complete and satisfactory that it has been found unnecessary to write restrictive purchasing specifications covering the physical properties and chemistry of the sheets, the main requirement being that the sheets should be satisfactory for the job in so far as breakage, surface after drawing, and bad metal is concerned. Bad metal includes such surface defects as slivers, fins, pits, and scratches which might develop only after the sheet has been drawn.

The sheet manufacturers will and are continuing to cooperate with the users of sheets to meet new requirements and to improve the present products. There is a large amount of work still to be done in the steel plant and rolling mill in the matter of making better drawing sheets. Particularly are there opportunities along the line of decreasing, or preferably, completely eliminating, the aging behavior which always develops if there is any abnormal delay in stamping sheets after they have been delivered. The very nature of the steel used in the production of sheets for drawing purposes at the present time makes this a rather difficult undertaking, but that the problem is not insurmountable has been demonstrated.

Acknowledgments

The author takes this opportunity to express his indebtedness to The American Rolling Mill Company for making available their facilities and also much of the data incorporated in this paper.

A Study of Lip Clearance on Twist Drills

By CHARLES J. STARR,[1] URBANA, ILL.

This paper discusses the form of the warped surface on twist drills called "lip clearance" as produced by five makes of drill-sharpening machines. Theoretically this lip-clearance angle should increase as measured from the circumference toward the center of the drill. So-called correct angles are assumed for various-diameter drills with a given feed, and illustrations show how much the drills actually vary from the correct angles. The contour of the lip-clearance surface is measured by a special measuring machine.

The drills are rotated by 10-deg increments and the dial-indicator pointer on the measuring machine moved a definite distance from center for each measurement. Thus, deviations of the surface from a true cone are measured. The angle is easily computed from these data. Detailed description shows how the lip-clearance surface is developed and a comparison is made of the actual with the assumed correct angle of clearance. Figures show the developed surfaces of $^3/_8$-in. and 1-in. drills as sharpened on these five drill-grinding machines. Some drills have beveled corners and a negative clearance may be noted on these because of lack of care in sharpening the drills. The developed surface of a drill with a thinned web shows how the possibility of rubbing back of the cutting edge in the web may be reduced.

The figures show that too much clearance is ground near the circumference of the drill in most of the cases studied. A few, however, approach quite near to the so-called correct angles.

The drills are tested on drill presses equipped with dynamometers in annealed cast iron at approximately 60 fpm surface speed. Torque and thrust curves are plotted to show the power required to operate these drills. Considerable variation will be noticed in the torque and thrust. The advantage of thinning the web is brought out quite positively in these curves. The paper suggests a future study to endeavor to ascertain if one machine sharpens drills that are better adapted for drilling one material than another, also that endurance tests should be run to test the life of drills between grinds. There is no intention to criticize the design of the various sharpening machines, but rather their operation.

THE SUBJECT of twist drills has been of considerable importance for a number of years, and many studies have been made. Most of these studies have dealt with characteristics of drills other than lip clearance, and a study of this feature has not been touched upon very much as far as the author has observed.

The shape of the lip clearance is of prime importance because it helps to form the cutting edge. An excess of clearance weakens the cutting edge. If, on the other hand, there is not enough clearance the drill cannot cut freely.

"Lip-clearance angle" is a term that may require defining, and for that reason, reference is made to Fig. 1 showing the end and side views of the point of a twist drill. The term "lip-clearance surface" is given to that surface which is so named in the plan view in Fig. 1. It is the surface directly back of the cutting edge or lip, and is the peculiarly warped surface that forms the clearance between the drill proper and the bottom of the hole that has been created by the drill.

[1] Associate in Mechanical Engineering, University of Illinois. Mem. A.S.M.E. Professor Starr has served as toolmaker with the Stanley Works, New Britain, Conn., toolmaker, die maker, and toolroom foreman with the New Britain Machine Company, New Britain, Conn.; tool designer with Pratt & Whitney Company, Hartford, Conn.; and later as planning engineer with the New Britain Machine Company. These positions were held at various times between 1908 and 1921. In 1921 he became assistant superintendent of the machine laboratory at the University of Illinois, and while thus employed studied for a B.S. degree in industrial education, which he received in 1933. In 1931 he was made instructor in mechanical engineering at the University of Illinois, and advanced to his present position in 1934.

Contributed by the Machine Shop Practice Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Object of Study

The object of this study is to obtain the contour of the lip-clearance surface as developed by various machines that are manufactured for sharpening twist drills. As is already known, it is necessary that the angles of clearance change as the drill is measured from the circumference toward the center, along the cutting edge.

The drill illustrated in Fig. 2 shows the feed per revolution. If the circumference of the drill is developed, a triangle is formed in which the circumference forms the base of the triangle, and the feed one side. The hypotenuse of the triangle gives the helix angle of feed of the drill, or in this case, angle AOB. Now as the diameter is reduced, and the center of the drill is approached, the feed remaining constant, the angle will increase until a condition is reached that will be considered as giving the angle $A'OB$. In this case, the circumference of the circle would be $B'O'$, instead of BO, as in the first instance. Thus, it is seen that the angle of clearance, or the form of the lip clearance, must change and become greater toward the center of the drill than near the circumference. The variations observed resulting from the measurement of this lip clearance led to the present discussion.

Method of Measuring

The method developed for measuring the lip-clearance angle led to the construction of the machine shown in Fig. 3. This apparatus consists primarily of a means of holding the drill and revolving it any number of degrees desired. A pointer comes in contact with the lip clearance of the drill and the drop of that face from a true cone is measured in thousandths of an inch.

A drill lined off to illustrate the circular and radial movements of the indicator pointer is shown in Fig. 4. By means of the compound rest on the measuring machine, it is possible to get the line of travel of the dial indicator parallel to the cutting edge of the drill.

When the drill is inserted in the collet in the headstock, it is rotated until the cutting edge stands in a horizontal position as is shown in Fig. 5A. This position is checked with a horizontal

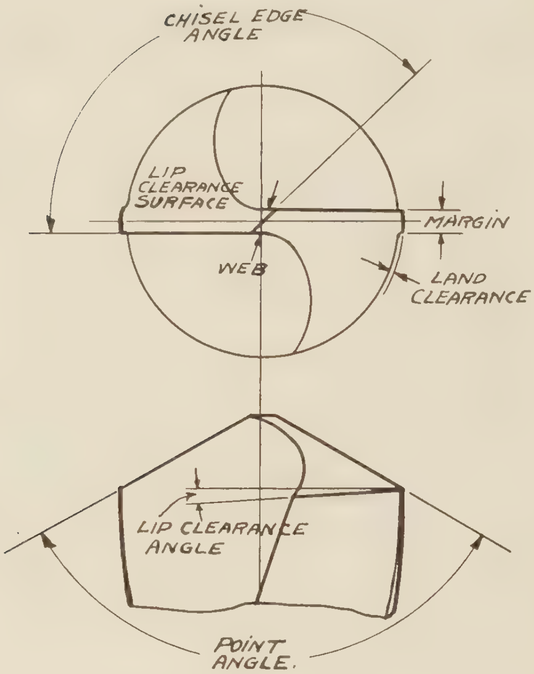

Fig. 1 The Drill With Parts Defined

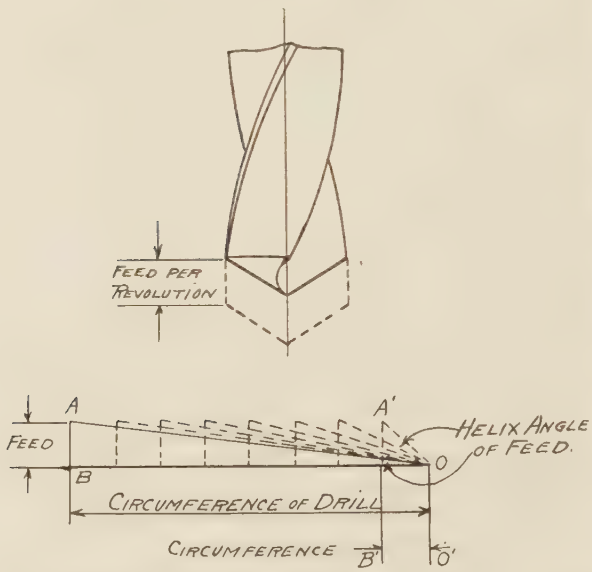

Fig. 2 Designation of Feed and Change in Helix of Feed

straightedge and a magnifying glass. A graduated dial at the left end of the headstock is then set at 0. The chisel-edge angle, such as 138 deg shown in Fig. 5*G*, is then determined by rotating the drill.

When operating this machine, the point of the indicator is set on center, both vertical and horizontal, with the center of the headstock of the spindle. By rotating the screw of the compound rest, the indicator, or point, travels along the face of the drill, from the center toward the circumference or from the center of Fig. 5*A* along the center line *BA*, from its center toward *A*. Thus, it is possible to find the point angle as shown in Fig. 5*F*, that is, angle 124 deg 20 min in this case.

The next step is to measure the angle of clearance. Fig. 5*A* shows how the drill is rotated with the indicator point set any desired distance from the center of the drill. As the pointer is moved by $^1/_{64}$-in. increments along radii from the drill center, the drill is rotated clockwise, for readings below center line *AB*, and counterclockwise for readings above center line *AB*. To explain this more thoroughly, take one increment and follow it through to obtain the measurement desired. Consider the radius of the circle as that shown by the line *O* to *C* in Fig. 5*F*, and divide this distance up into sixty fourths as shown in Fig. 5*A* and 5*B*. The divisions are represented by the various circular lines shown of these two figures. If the $^1/_8$-in. circle is considered as an example, the circular line XY shown in Fig. 5*A* will represent that part of the circle which passes over the clearance surface of the drill, *X* representing the point where the circle passes through the cutting edge, and *Y* the point where it intersects the flute of the drill.

If a cylinder with $^1/_8$-in. radius, having its axis coincident with that of the drill, is passed through the clearance face, it will cut it as shown in Fig. 5*F* where the cylindrical surface *PQ* cuts the clearance face, and will be the segment of a circle *XY* as shown in

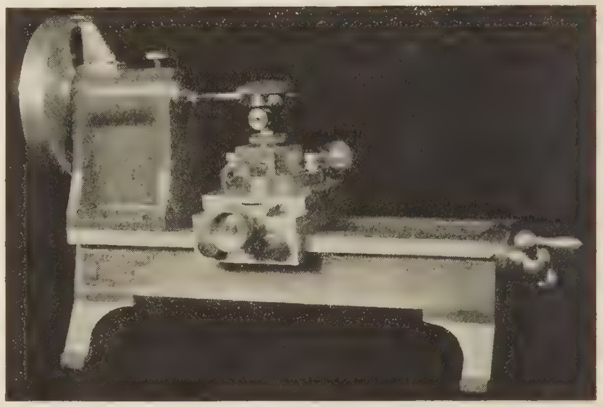

Fig. 3 Machine for Measuring Lip Clearance

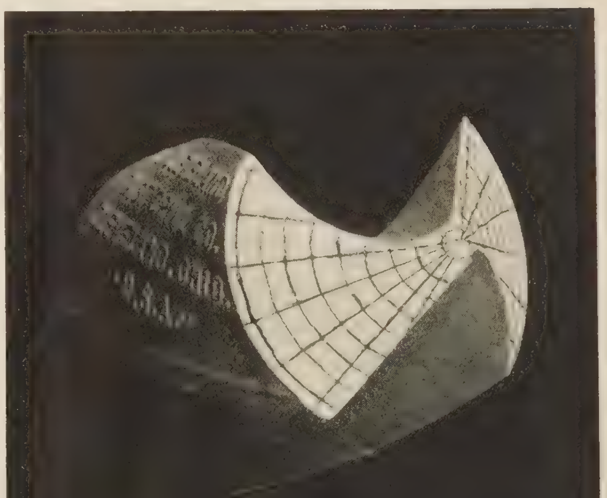

Fig. 4 Enlarged Point of Drill Lined off to Illustrate Circular and Radial Movements of the Indicator Shown in Fig. 3

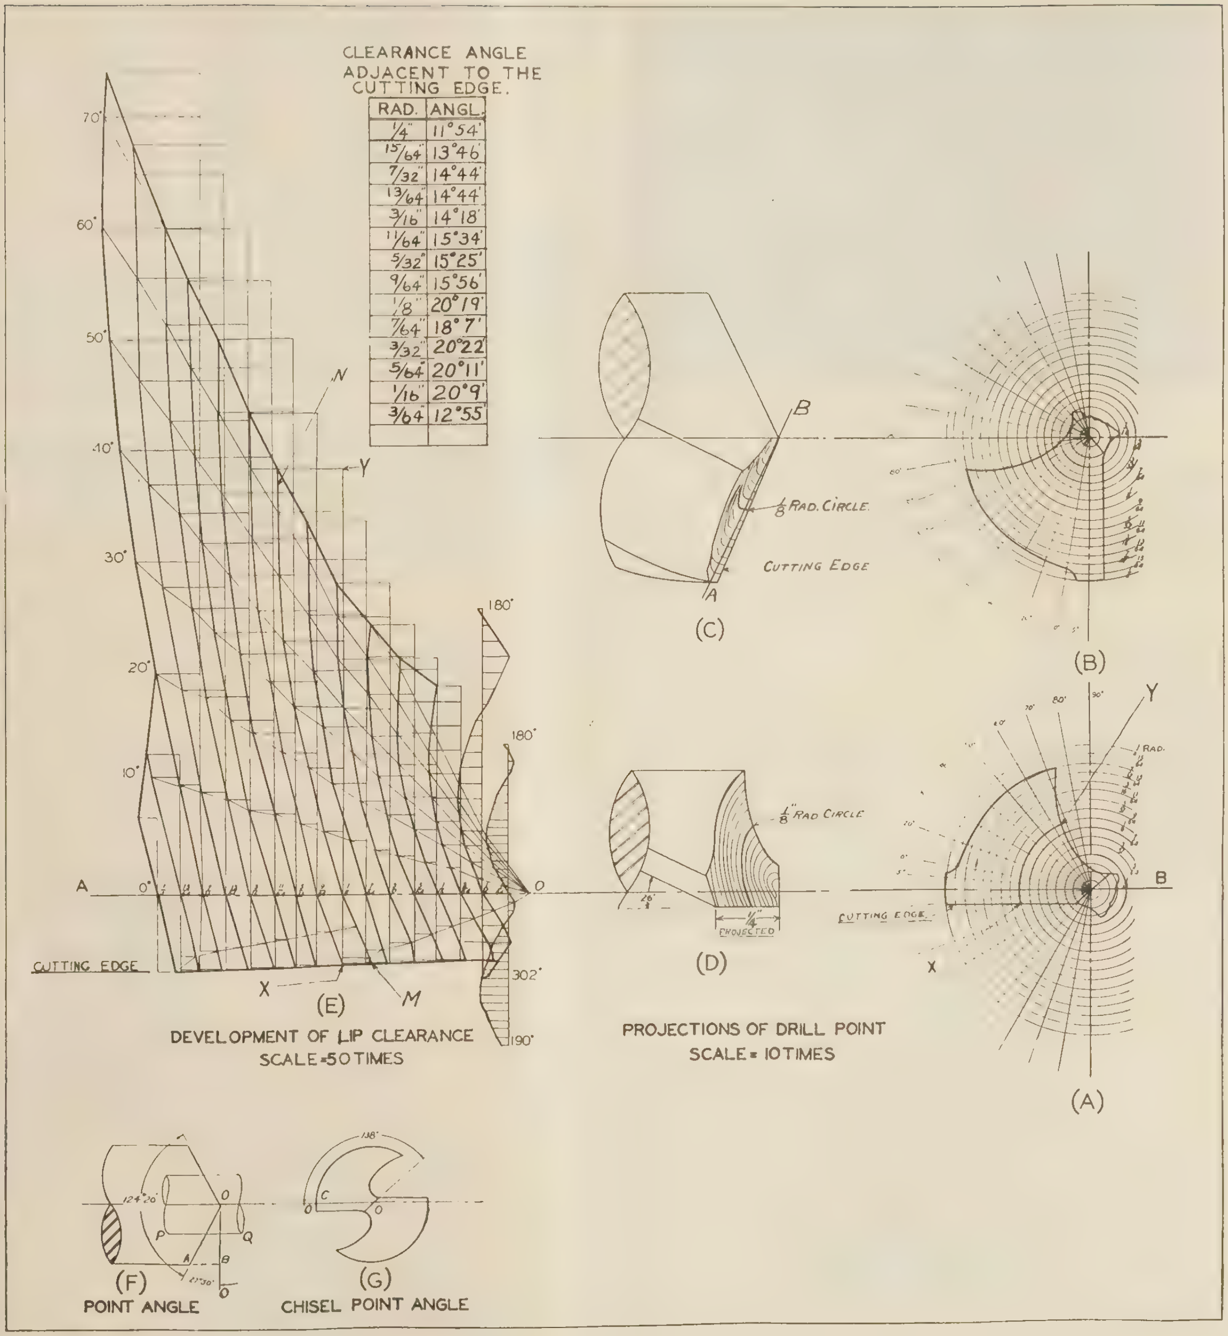

FIG. 5 STUDY OF LIP CLEARANCE OF 1/2-IN. TWIST DRILL

Fig. 5*A*, but as this intersection is looked at from a different angle, it will appear as shown in Fig. 5*D*. It appears as an irregularly curved line, with relation to the cutting edge, because the end of the drill is not a true cone, due to the clearance ground on it.

As the surface drops away from the cutting edge, the distance from the true cone to the clearance face will increase with the result that a peculiar curve is shown by a 1/8-in. radius circle shown in 5*D*. The distance between the true circle and the irregular curve, shown in Fig. 5*D*, is measured on the dial indicator, as the drop or clearance of the cutting edge for any given distance.

To show this drop, that is, the form of the lip-clearance angle and its deviation from a true cone, the surface is developed as is shown in Fig. 5*E*.

In Fig. 5*F* it will be found that the triangle *AOB* has *AO* as the cutting edge of the drill and *BO* as the radius. Therefore *AB* is the projection of *AO* on the line *AB*, and the distance called 1/4 in. in Fig. 5*D* is this projection. Since this particular drill is 1/2 in. diameter and the cutting edge is to be measured by 1/64-in.

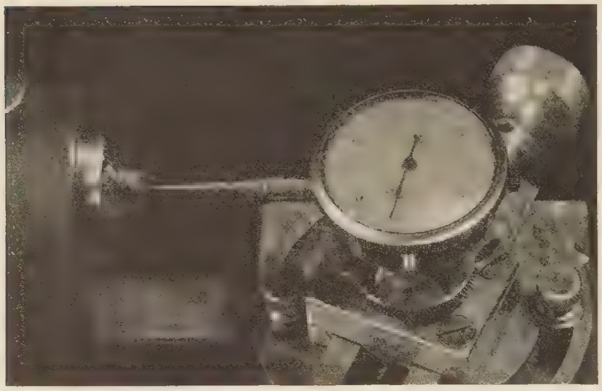

Fig. 6 A Drill Being Measured for Clearance

increments, the line AB in Fig. 5F is divided accordingly. That part of the circle as shown by XY in Fig. 5A is developed and now appears as a straight line XY in Fig. 5E, and the clearance is represented by the heavy line MN. The other light lines in Fig. 5E show the construction, how the distance changes by 10-deg increments, and how the angle of clearance forms a curve, and not a straight line.

TABLE 1 DRILL FEEDS USED IN PRACTICE, AND AVERAGE FEEDS USED BY THE AUTHOR IN THIS PAPER

Drill diameter, in.	Feeds used in practice, in. per rev Minimum	Maximum	Feeds assumed as average by the author, in. per rev
1	0.014	0.050	0.040
3/8	0.008	0.013	0.012
5/16	0.007	0.012	0.010
1/4	0.006	0.010	0.008
3/16	0.005	0.007	0.006
1/8	0.004	0.006	0.005

When reading the dial indicator, as the drill is measured, those values that occur to the right of zero on the dial shown in Fig. 6 are considered as plus and those to the left of zero are considered as minus. This method of designation is used as a convenience when laying out the developed view as shown in Fig. 5E. Plus values are placed to the left of the vertical line and minus values to the right.

It is also possible to notice that the angle of clearance at the circumference C is less than the angle of clearance near the center. The table accompanying Fig. 5 shows the clearance angle at a distance approximately equal to 10 deg back from the cutting edge. Drills ground on five types of drill grinders were measured in the manner just described.

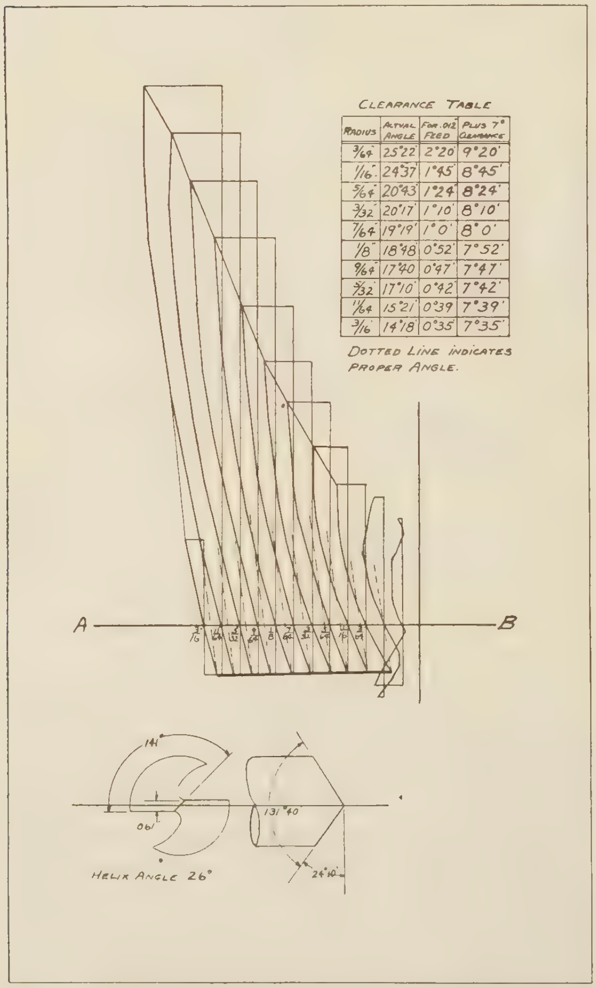

Fig. 7 Point Study of 3/8-In. Drill Sharpened on Machine A

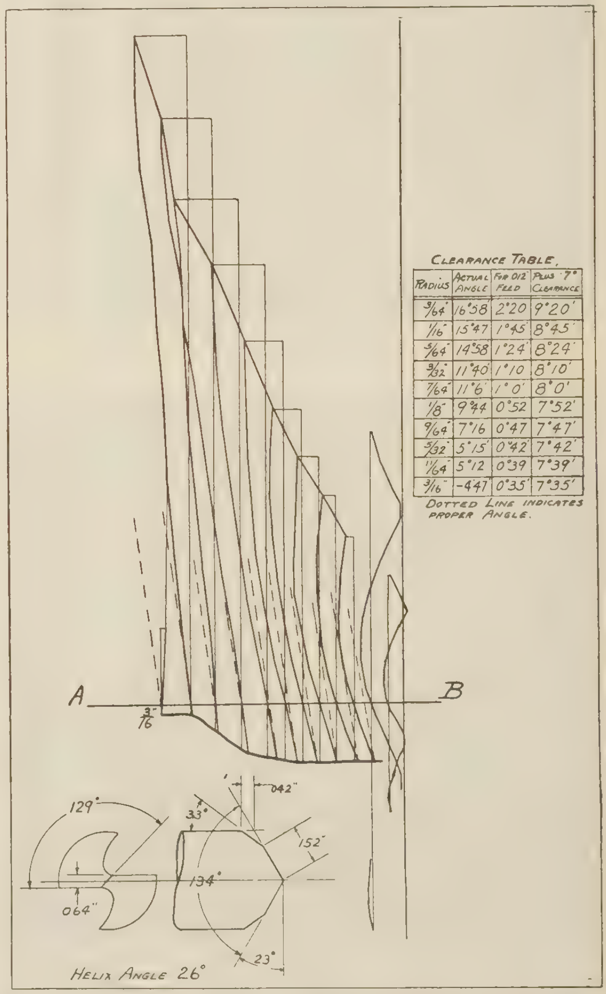

Fig. 8 Point Study of 3/8-In. Drill Sharpened on Machine B

The Angle of Feed

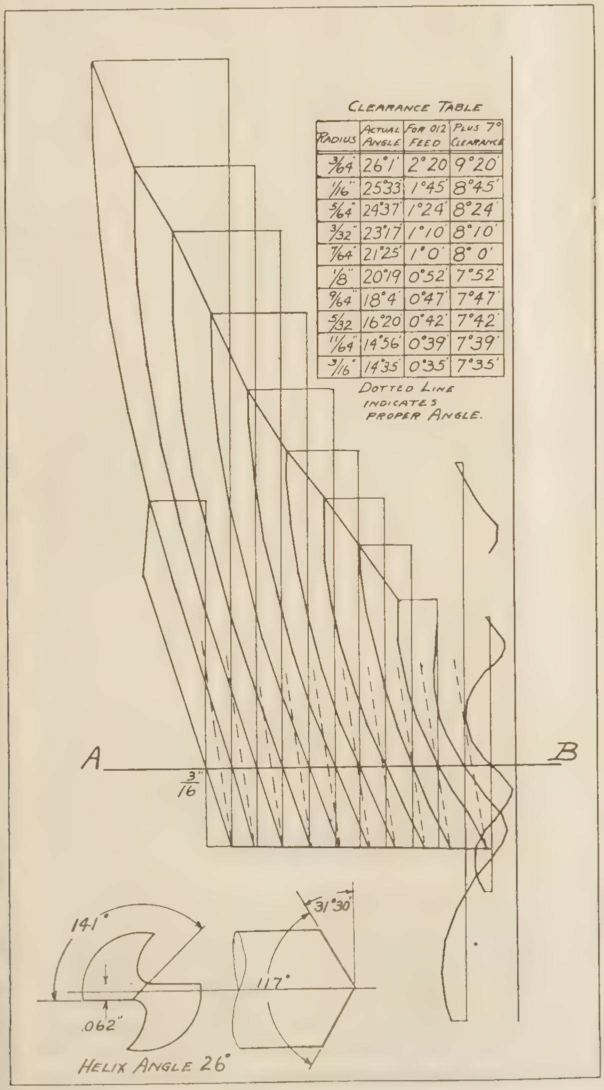
The question which immediately presents itself is: "What should be the correct angle?" It is necessary that one should know before this question is answered what the correct feed is for any given size drill? Apparently, a standardized feed for a given drill is impossible, because of varying conditions of machine and material, as well as quality of the drill. Therefore, as a basis on which to work, it is necessary to assume given feeds for given size drills. For this purpose, the author took feeds for these given size drills from the actual practice of various users and drill manufacturers, and from the data gathered assumed an average feed, which average feed is used throughout the remaining part of this paper. The feeds used in practice as obtained from users and manufacturers of drills, together with the average feed for each size of drill as assumed by the author, are given in Table 1.

Helix angles were developed from the author's assumed values of feeds by the method shown in Fig. 2. The feed specified for a given diameter of drill and the angle was figured from the circumference to the center for changes in diameter by $^{1}/_{32}$-in. increments. The results obtained from these drills, sharpened by different methods, are extremely interesting.

Developed Curves

In Figs. 7, 8, 9, and 10 are shown studies of the points of $^{3}/_{8}$-in. drills ground on four different types of machines, hereafter designated as machines *A*, *B*, *D*, and *E*. A clearance table is included with each figure which shows the actual clearance by $^{1}/_{64}$-in. increments from the center to the circumference as compared with the feed angle required for the feed for that given diameter, the feed being the author's assumed values given in Table 1. Of course, it must be realized that clearance above the angle of feed must be maintained so that the cutting edge will clear and actually cut. For that reason, a clearance angle of 7 deg has been arbitrarily assumed, and this angle, added to the angle of feed, appears in the fourth column of the table shown with each of these figures. The dashed lines in each figure indicate what may be assumed to be the proper angle.

It may be observed, after examining these figures, how much the actual cutting angle differs from that which is required in



Radius	Actual Angle	For 012 Feed	Plus 7° Clearance

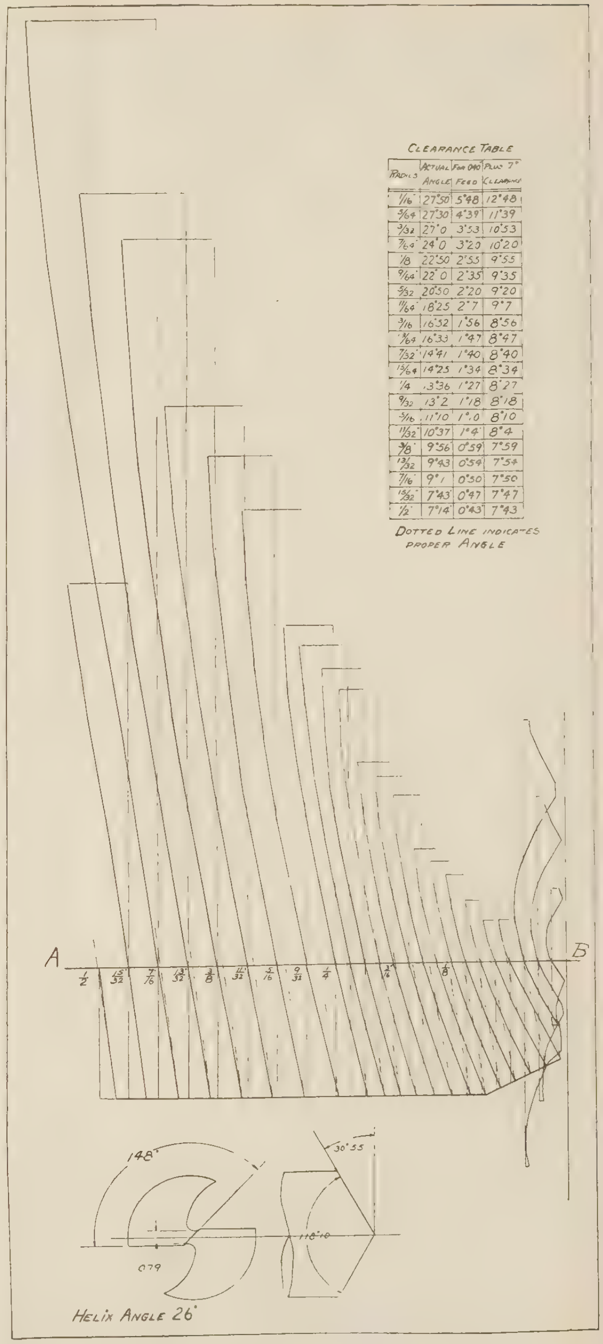

FIG. 12 POINT STUDY OF 1-IN. DRILL WITH POINT THINNED, SHARPENED ON MACHINE *A*

order that the drill may cut at the feed designated. The drills sharpened on machine *A* have a comparatively straight cutting edge, while those sharpened on machines *D* and *E* have an extreme angle of clearance. Of course, the angle of clearance that is very far back of the cutting edge is unimportant; however, the excessive angle shown in Fig. 10 seems unnecessary. If the angle is not great enough, the drill will rub back of the cutting edge and will be unable to free itself. If the angle is too great, the cutting edge is much too weak.

It will be noticed that the point angle on these drills varies considerably from that which is usually considered as proper, namely, 118 deg included angle. Even drills ground in the same machine, although the sizes vary, do not necessarily have the same angle. The same peculiarities are found, as are shown, in the other sizes. In this group, attention is called to drills ground on machine *B*, and the peculiar shape of the point will be noted. There are two angles on the point. In other words, the corners are beveled or rounded off to insure longer cutting life of the drill. This gives the peculiar cutting-edge form shown in Fig. 8.

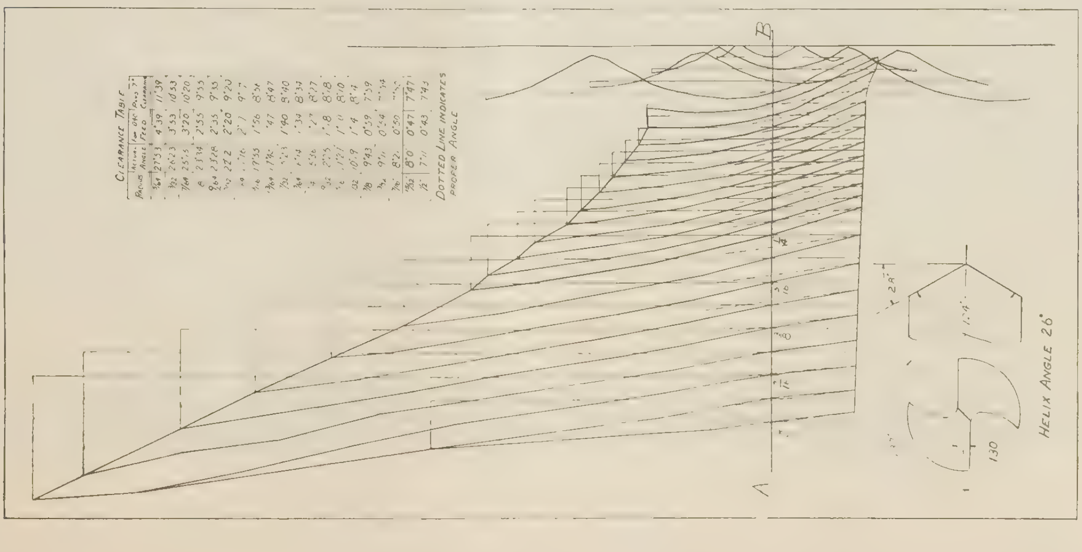

FIG. 13 POINT STUDY OF 1-IN. DRILL SHARPENED ON MACHINE *B*

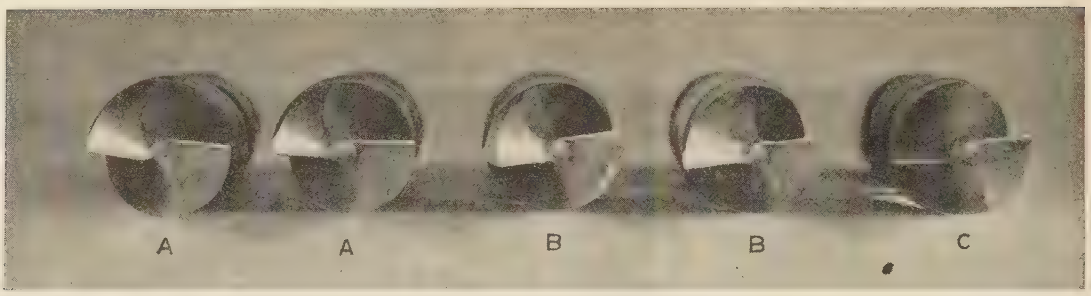

Fig. 16 Condition of Points of 1-In. Drills After the Tests

The action of rounding the corner on a twist drill is not new. This was discussed by Benedict and Lukens in their investigation of drills in 1917.[2]

Fig. 10 showing the drill sharpened on machine E gives the same peculiar curve as obtained in the other drills sharpened on this same machine. It shows an unusual amount of clearance, and yet the curve swings back to the right, which means that all of the clearance is not available as may appear from the first look at the figure.

Figs. 11, 12, 13, 14, and 15 show 1-in. drills ground on machines A, B, and C, respectively. Fig. 11 shows a drill that comes as close to the theoretical—if it may be called that—of any that

[2] "An Investigation of Twist Drills," Part I, by B. W. Benedict and W. Penn Lukens, Engineering Experiment Station Bulletin No. 103, November 26, 1917, pp. 80–82. University of Illinois, Urbana, Ill.

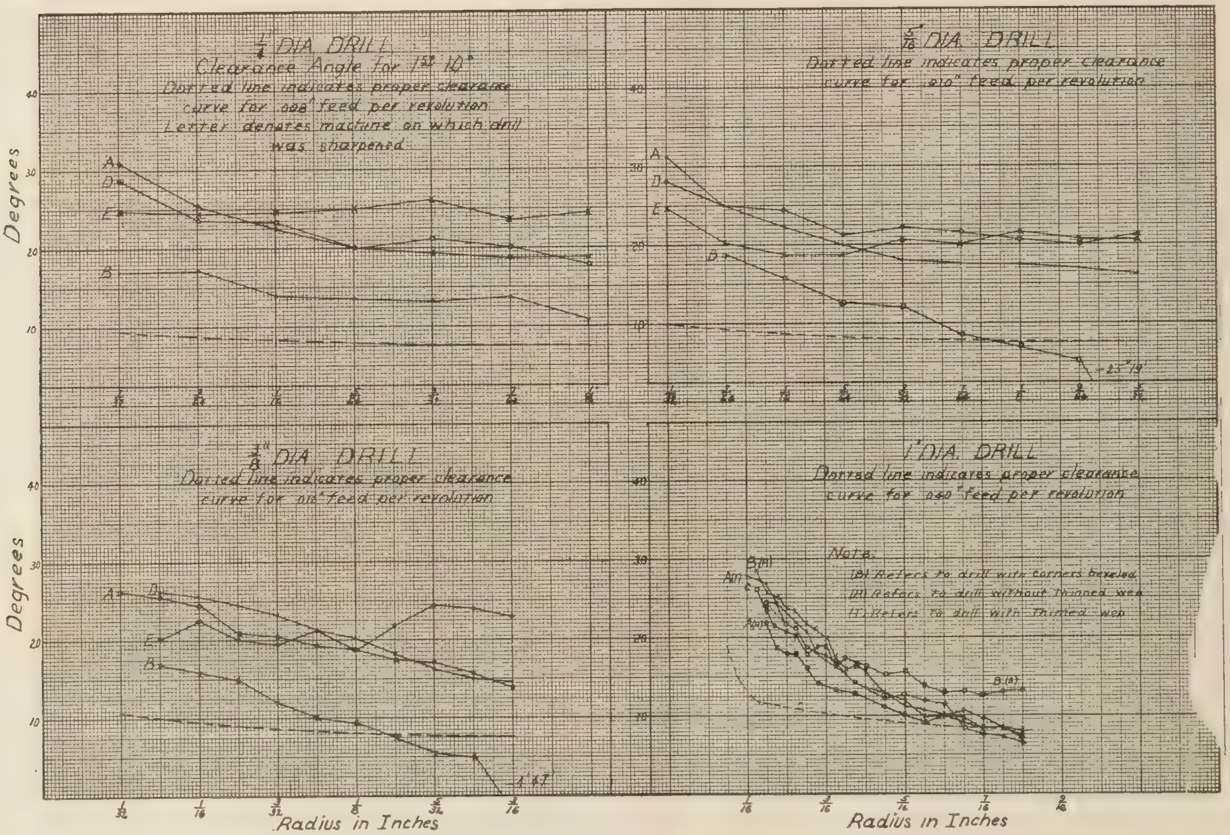

Fig. 17 (Top Left) Comparison of Summarized Clearance Curves for 1/4-In. Drills

(Letters on curves denote the machine on which the drills were sharpened. The dashed line indicates the proper clearance curve for a feed of 0.008 in. per revolution. Clearance angle for the first 10 deg.)

Fig. 18 (Top Right) Comparison of Summarized Clearance Curves for 5/16-In. Drills

(Dashed line indicates proper clearance curve for a feed of 0.01 in. per revolution. Letters on curves indicate the machine on which the drills were sharpened.)

Fig. 19 (Bottom Left) Comparison of Summarized Clearance Curves for 3/8-In. Drills

(Dashed line indicates proper clearance curve for a feed of 0.012 in. per revolution. Letters on curves indicate the machine on which the drills were sharpened.)

Fig. 20 (Bottom Right) Comparison of Summarized Clearance Curves for 1-In. Drills

(Dashed line indicates proper clearance curve for a feed of 0.04 in. per revolution. Letters on curves indicate the various drills shown in Fig. 16. The letters in parentheses indicate condition of grinding as follows: (B) refers to drill with corners beveled, (R) refers to drill without thinned web, and (C) refers to drill with thinned web.)

have as yet been discussed. At the $^1/_2$-in. radius, it will be found that the actual angle of clearance is 8 deg 12 min while the so-called "correct angle" would appear as 7 deg 43 min. However, near the center, much more clearance appears than is actually needed. If these curves are followed, particularly the $^3/_{32}$-, $^7/_{64}$-, and $^1/_8$-in. curves, it will be found that they have a tendency to bend to the right, which means that there is likely to be an interference there, or a rubbing action of that part of the drill against the material being cut.

Fig. 12 shows a 1-in. drill ground on the same machine as the one illustrated in Fig. 11, but in this case, with the point thinned. This shows that the trouble already mentioned as appearing in Fig. 11 is eliminated, because the curve of the lip-clearance surface is not as long.

All the drills discussed so far, the author believes, have been sharpened with the drill being held with its axis in a horizontal plane. This means that any changes, due to wear, on the face of the wheel will be likely to be reproduced in the lip-clearance angle, and the cutting edge will not necessarily be a straight line. It has been found in some cases that the cutting edge deviated as much as 0.040 in. from a straight line.

Fig. 13 shows a 1-in. drill as ground on machine *B* with a standard point. Fig. 14 shows a drill ground on the same machine, but with the corners beveled. This gives a peculiar cutting edge, as was noticed in the smaller sized drills.

In Fig. 15 is shown a development of the drill ground against the face of the wheel, but in this case, the drill is held with its axis in a vertical plane. It will be noticed that the curves of clearance come nearer to approaching straight lines than do most of those heretofore shown. However, trouble occurs toward the center of the drill, as has been mentioned before, by the drill rubbing back of the cutting edge.

The condition of the 1-in. drills after testing is shown in Fig. 16. The difference between the two drills *A* will be noted. The one on the left has the point thinned. Less rubbing action will be noted at the chisel edge than in the other drill marked *A*. With drill *C* considerable rubbing action has taken place as is shown by the ball of metal at the chisel edge. The same holds true with the drills marked *B*.

In Figs. 17, 18, 19, and 20, the curves of the drills as ground on various machines are summarized and compared. The degrees of clearance are plotted against radii. It will be noticed that the curves are extremely peculiar, and show little similarity.

The dashed lines represent what would be the correct clearance curve with a feed that has been assumed for a given diameter and an additional allowance of 7 deg clearance. As shown in Fig. 17, $^3/_8$-in. drills show an even greater variation, but the curves for 1-in. drills in Fig. 20 lie reasonably close together.

Figs. 21, 22, 23, and 24 show curves wherein the drills are classified, according to the machine, on which they are ground. The curves for drills ground on machine *A* shown in Fig. 21 lie reasonably close together except the curve for the $^1/_8$-in. drill.

Fig. 22, for drills ground on machine *B* show curves for the two 1-in. drills that lie quite close together, but the smaller drills

(Letters on curves indicate machine on which drills were sharpened.)

seem to vary considerably. With machine *D*, curves for which are shown in Fig. 23, this variation is increased much more. In this case, the drills are all ground on the same size machine.

The curves for a group of drills ground on machine *E* are shown in Fig. 24. The fact that these curves do not lie together, shows that the method of holding the drill or method of locating the drill on the holder is such that the operator can make a mistake and not clamp all drills the same. This condition apparently holds true for drills ground on machine *D*.

The curves for drills ground on machine *B*, which are shown in Fig. 22 run reasonably close together, for the small and also large drills, and yet, a wide variation between the two groups, while the curves for drills ground on machine *A*, shown in Fig. 21, lie to a great extent together even though in this case, the small drills are ground on one size of machine, and the large drills ground on another.

After studying the clearance angles of these various drills, they were tested in machines equipped with dynamometers. The 1-in. diameter drills were tested on the drilling machine used by Benedict and Hershey.[3] The small drills were tested on a high-speed drilling machine and dynamometer developed by the author. Torque and thrust were taken by springs and the deflection of these springs registered on dial indicators. The springs were calibrated in place on the machine against known loads and calibration curves established. These drills were tested in commercial iron that had been cast in the university foundry. The cutting speed for the drills was approximately 60 fpm. The blocks were annealed and the Rockwell hardness found to average 77.5 B on the large blocks and 76 B scale on the small blocks. The chemical composition of these blocks was 2.18 silicon, 0.081 sulphur, 0.57 phosphorus, 0.52 manganese, 3.50 carbon.

In Figs. 25, 26, 27, and 28 are shown torque and thrust curves for drills tested. These curves show that no set of drills as sharpened on any particular machine may be considered superior to another, in so far as torque and thrust are concerned except in the case of the 1-in. drill with the thinned point. Here a slight difference will be noticed in the torque curve, but a considerable difference appears in the thrust curve as may be expected.

Examination of the holes drilled showed that all drills cut about the same as to size and finish except those drills with the beveled corners. These drills produced holes that were nearer to the drill size and had a better finish than holes produced with drills having standard points. This fact is not considered as showing a superiority of grinding machine *B*, because the same might have resulted if drills had been beveled after sharpening in the other machines.

The beveling of the corners did show a decided factor in endurance tests of $^3/_8$-in. drills. These tests were run using test

blocks of S.A.E. 6150 steel. This steel had been normalized and had a Rockwell hardness of 92 B. A sulphurized mineral oil was used as a coolant. A surface speed of 166 fpm and a feed of 0.0085 in. per revolution were used. All drills ground with the standard point failed early in the test while the drills with beveled corners did not fail at all and appeared in very good condition at the end of the test.

The results of this test were as follows: A drill ground on machine *A* drilled 5 holes, 1 in. deep; a drill ground on machine *B* drilled 11 holes, 1 in. deep and was still in good condition at end of test; a drill ground on machine *D* drilled 2 holes, 1 in. deep; and a drill ground on machine *E* drilled 4 holes, 1 in. deep. The only reason that drill *B* was not run to destruction was that the test material was exhausted.

A summary of the torque and thrust data is shown in Table 2. An analysis of this table shows, more completely, the results that have been plotted in Figs. 25, 26, 27, and 28. A study of the figures given in Table 2 confirms the statement previously made that no grinding machine is superior to another in all cases. The only real difference occurs in the drill with the thinned point.

The small drills were copper-plated on the point, the better to detect any rubbing that might occur. On the 5/16-in. and 1/4-in. drills, that were sharpened on machine *B*, considerable rubbing was detected on the beveled corners.

It is hoped that this paper will suggest a future study of this subject at which time drills sharpened on various machines should be tested in different materials. Complete endurance tests should also be run for it seems possible after this study of the lip-clearance angle that one grinder may have points that make it superior for sharpening drills for different materials or other conditions of use. The author intends to continue this study in the near future.

In closing, it might be well to state that in this study, there is no intention to criticize the design of the various drill-sharpening machines used, but rather to criticize the operators of these machines. Too often, the operator does not use proper caution when setting the drill preparatory to sharpening it. It does appear, however, that one might well raise the question of making these machines as near foolproof as possible so that the operator cannot go wrong, and must necessarily reproduce time after time the point that the machine manufacturers intended should be produced on their machines.

Acknowledgments

The results presented in this paper were obtained in connection with an investigation conducted by the Engineering Experiment Station, of which M. L. Enger, dean of the college of engineering, is the director, in the department of mechanical engineering of which O. A. Leutwiler, professor of mechanical engineering design is head. These results will ultimately comprise part of a bulletin of the Engineering Experiment Station. Acknowledgment is also due the Latrobe Company of Latrobe, Pennsylvania, for furnishing the small drills; also, to the various manufacturers of drill-grinding machines for sharpening the drills used in these tests.

The Economic Characteristics of Typical Business Enterprises

By WALTER RAUTENSTRAUCH,[1] NEW YORK, N. Y.

This paper presents the results of analyses of the relationship between incomes and expenses of a wide range of types of business, over a period of years during which incomes and expenses expanded and contracted greatly. The data upon which these analyses were based were taken principally from the published financial statements found in Moody's Financial Manual, Poor's Financial Manual, Crandall's Corporate Analyst, and various government publications.

The results of these analyses indicate that business enterprises may be compared with each other in ways heretofore impossible and as a result of such comparisons their relative economic worths may be judged.

IT HAS been suggested[2] that the total expenses of every business enterprise tend to vary with income according to the general equation

$$\text{Total expense} = a + bx$$

where a = constant total expense, bx = variable total expense, x = income.

This paper presents the results of analyses of the relations between incomes and expenses of a wide range of types of business, over a period of years during which incomes and expenses expanded and contracted greatly. The technique devised to determine the trend of expense with income was as follows:

A 45-deg line was drawn on a sheet of cross-section paper and equal scales were used for both horizontal and vertical measurements. The incomes for each year were laid off along the base to scale, as shown in Fig. 1 at oa, oa', and oa'', and verticals drawn through the points a, a', a'' terminating at the 45-deg line at b, b', and b''. Thus $ab = oa$ = income. The corresponding total expenses were laid off to scale along the appropriate verticals as shown at c, c', and c''. A trend line drawn through the points c, c', and c'' by inspection, determined the relation between expense and income.

[1] Professor of Industrial Engineering, Columbia University. Mem. A.S.M.E. Mr. Rautenstrauch was graduated from the University of Missouri in 1902 with the degree of bachelor of science. In 1902–1903 he was instructor at the University of Maine where he received the M.S. degree, and from 1904 to 1906 he was assistant professor at Cornell University. He received the degree of LL.D. in 1932 from the University of Missouri. He has occupied his present position at Columbia University since 1906, and is also consulting engineer to various manufacturing industries. He is a member of the National Research Council and numerous societies and is the author of a number of books; he has contributed many articles to the technical press and is a recognized authority on technology.

[2] "The Economic Characteristics of the Manufacturing Industries," by Walter Rautenstrauch, Mechanical Engineering, vol. 54, November, 1932, p. 759.

Contributed by the Management Division for presentation at the Semi-Annual meeting of The American Society of Mechanical Engineers, to be held in Detroit, Michigan, May 17 to 21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 W. 39th Street, New York, N. Y. and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

These studies show that the relationship between expense and income for many businesses follows closely the general law suggested in the earlier paper.[2]

Those few companies, for which the relation between income and expense is found to be somewhat erratic at times, seem to have either adjusted their selling prices drastically or have failed to follow a consistent policy of operations during the times when these erratic behaviors appear. The data upon which these analyses are based were taken principally from the published financial statements found in Moody's Financial Manual, Poor's Financial Manual, Crandall's Corporate Analyst, and various government publications.

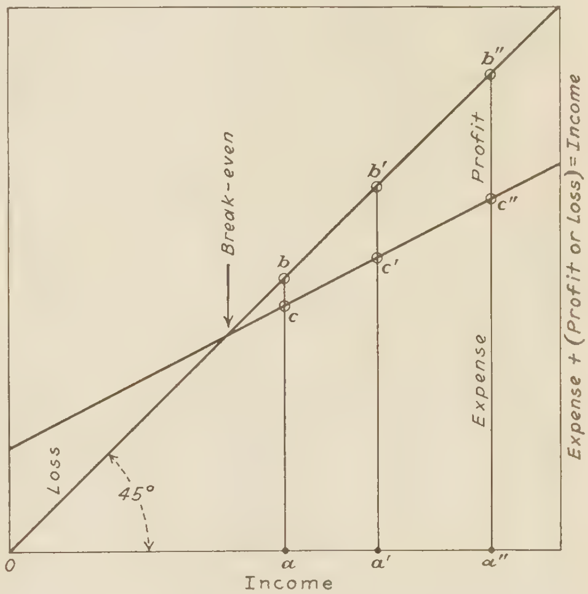

Fig. 1

The results of these analyses also indicate that business enterprises may be compared with each other in ways heretofore impossible and as a result of such comparisons their relative economic worths may be judged. Such comparisons are made and discussed in the following pages.

A The Automobile Industry

1 *The General Motors Corporation*

The financial reports of this company from 1909 to 1934 compiled in Poor's Financial Manual were analyzed and the relations between annual incomes and total expenses for the period of 25 years were plotted as shown in Fig. 2. There appear to be three distinct groups of trends of the total expenses. From 1909 to 1919 when the company was in its formative period, the relation between income and total expense shows no specific trend, due perhaps to the fact that new developments and additions brought about varying conditions from year to year. The company expanded very rapidly from 1920 to 1928 during

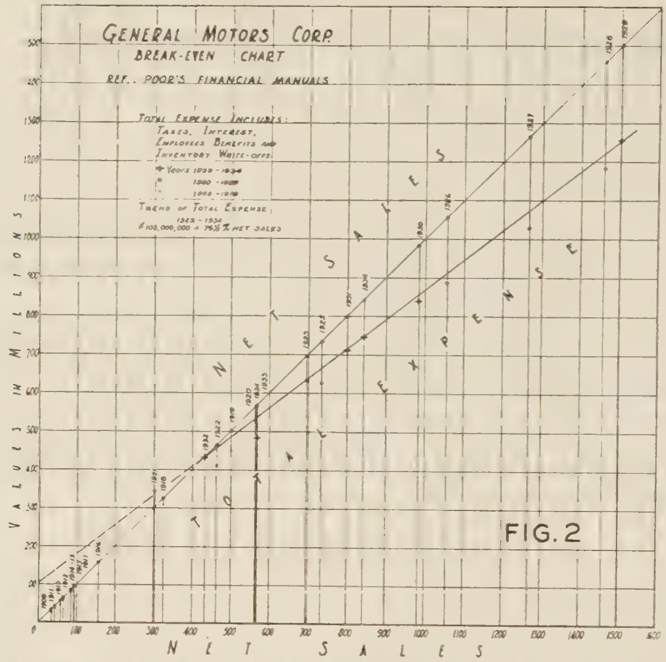

FIG. 2

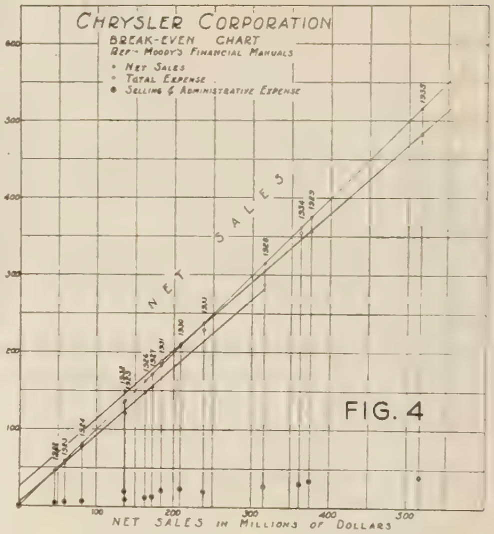

FIG. 4

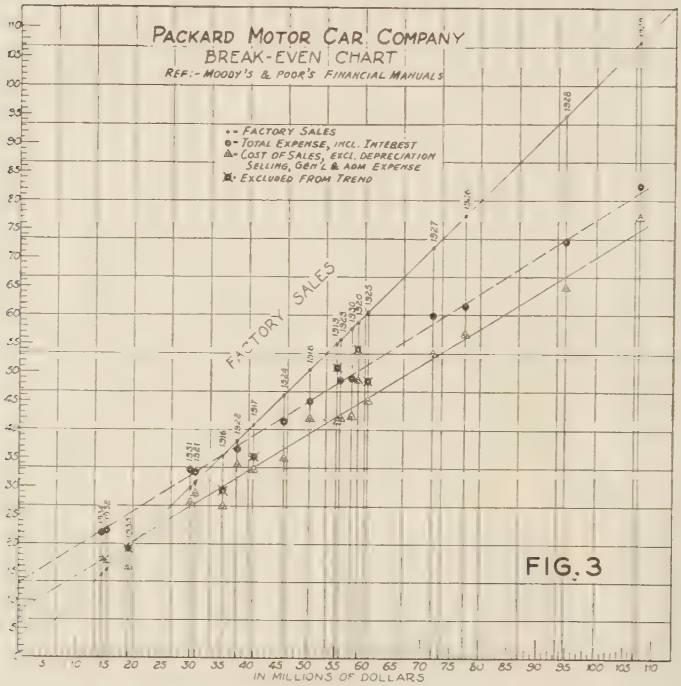

FIG. 3

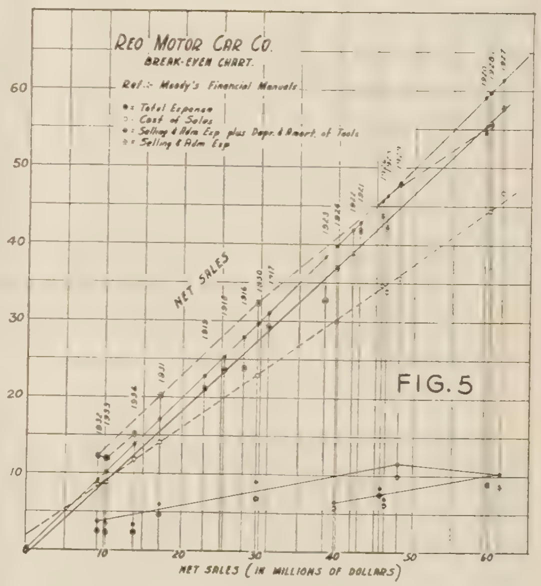

FIG. 5

which time it began to show a more definite trend of total expense to income. In 1929 the company experienced its maximum income (approximately $1,500,000,000) and then in common with all industries its sales declined to less than 30 per cent of the maximum in 1932. Since that date income from sales has increased each year and in 1934 was over $840,000,000. During the period from 1929 to 1935 the trend between income and total expense is very definite except for the year 1932 when it appears that the total expenses reported were exceptionally low. It is interesting to note that not only did the total expenses for the years 1930, 1931, and 1932 recede along definite trends, but that they are tending to follow the same trends upward as the income from sales increases. The present trend of total expense seems to follow the expense line shown in Fig. 2.

The equation of total expense is

$$\text{Total annual expense} = \$105{,}000{,}000 + (76.5 \text{ per cent of net sales})$$

Since this chart was constructed and the total-expense line and its equation were determined, the General Motors Corporation has issued its financial report for the year 1935. This report shows annual net sales of $1,155,641,510 and total expenses of

$988,210,920. The equation of annual total expense gives the result $989,065,755 which is less than $^1/_{10}$ of 1 per cent from the actual expense reported. More recently the company reported the results of operations for the first quarter of 1936 to be net sales of $341,306,065 and total expenses of $288,841,891. The equation of annual total expense for this company reduced to a quarterly basis is

Quarterly total expense = $26,250,000 + (76.5 per cent of net sales)

Applying this equation to the net sales reported for the quarter, the result is $287,349,000 or approximately $^1/_2$ of 1 per cent of the total expense reported for the quarter. Apparently this company is being operated with surprisingly close control of total expense in relation to income and therefore the total expenses and hence the profit from operations can be closely approximated for any annual or quarterly sales income by the use of the foregoing equations.

The equation of annual profit for this company is obviously found, from the equation of annual expense, to be

Annual profit = (23.5 per cent of net sales) — $105,000,000

The quarterly profit is accordingly

Quarterly profit = (23.5 per cent of net sales) — $26,250,000

The annual sales at which the company will break even may be found from the equation of annual profit by finding the net sales for which the annual profit is equal to zero. Thus the annual break-even point of this company is

Annual break-even point = $447,000,000

In summary, the economic characteristics of the General Motors Corporation are, for the period 1929 to 1935:

Fixed expense point	(annual) =	$105,000,000
	(quarter) =	26,250,000
Variable expense factor	=	0.765
Total expenses	(annual) =	$105,000,000 + (76.5 per cent of sales)
	(quarter) =	26,250,000 + (76.5 per cent of sales)
Profits	(annual) =	(23.5 per cent of sales) — $105,000,000
	(quarter) =	(23.5 per cent of sales) — $ 26,250,000
Break-even point	(annual) =	$447,000,000

2 Packard Motor Car Company

The financial reports of this company as published in Moody's and Poor's Financial Manuals for the years 1916 to 1934 were analyzed and the results charted as shown in Fig. 3.

The line of total annual expenses in relation to annual income was drawn to define the predominant trend. Only six years of the total of 19 plotted, fall far outside of the trend; two of which are war years (1916–1917) and one (1920) was a year during which many companies had comparatively high labor costs. However there are probably better explanations of these variations which could be found if one had access to the details of the accounts. From 1918 to 1934 a period of 17 years, with the exception of 1933, the trend of annual total expenses is found to be

Annual total expenses = $13,000,000 + (63.2 per cent of factory sales)

Quarterly total expenses = $3,250,000 + (63.2 per cent of factory sales)

The other general economic characteristics of this company are found to be:

Annual fixed expense point	= $13,000,000
Variable expense factor	= 0.632
Annual profit	= (36.8 per cent of factory sales) — $13,000,000
Annual break-even point	= $35,300,000

3 Chrysler Corporation

The break-even chart of this company is shown in Fig. 4. From 1922 to 1928 the total-expense line is the lower of the two shown in the chart, while from 1929 to 1935 the total annual expenses follow the trend shown in the upper line. The fixed charges of the company were increased materially after 1928 so that the break-even point was raised from approximately $40,000,000 to $227,000,000. This increase is due in part to an increase in administrative and selling expenses in greater proportion to sales income after 1927, as shown near the bottom of the chart. A shift of the trend line of total expense in relation to sales income may also be caused by a lowering of prices. Since this chart shows always the *relation* between income and expense, a shift in the trend of expense may be brought about by either a change in expenses or a change in selling prices, or both. Note for example, the incomes and expenses for 1929 and 1934 in which the expenses in the two years are approximately equal. If 1934 prices had been higher by approximately $3^1/_2$ per cent then both expenses and incomes for 1929 and 1934 would have coincided, that is, the expense point for 1934 would have shifted horizontally to the right while the income point would have traveled up the 45-deg incline to coincide with 1929.

We have not sufficient information on the details of prices and expenses of this company to state why the expense line shifted for the period 1929 to 1935, above that for the period 1922 to 1928. The interesting point is that there are these persistent straight-line relationships between income and expense for a span of years and over a wide range of sales. If the period for 1929 to 1935 is an indication of present trends, then this company appears to have the following economic characteristics

Annual fixed expense point	= $25,000,000
Variable expense factor	= 0.89
Equation of annual total expense	= $25,000,000 + (89 per cent of net sales)
Equation of annual profit	= (0.11 of net sales) — $25,000,000
Break-even point (annual)	= $227,270,000

After the above analysis was made and during the preparation of this text, the New York Times reported July 25, 1936, that the sales and net profits of the Chrysler Corporation for the 6-months period ending June 30, 1936, were $358,634,899 and $29,473,736, respectively. The total expenses for this period are therefore $329,161,163. The equation of average total expense for a six-months period is

Avg 6-months total expense = $12,500,000 + (89 per cent of net sales)

According to this equation the probable total expense for this period should be $331,685,000, which is $2,520,000 or about 0.76 per cent greater than the actual expense. Departures from this amount are to be expected because of differences in interest and other charges from year to year as the following comparative statements quoted from the report in the New York Times show

Income Accounts Compared

(Consolidated income account for the six months ended on June 30th)

	June 30, 1936	June 30, 1935
Sales	$358,634,899	$295,569,895
Cost of sales	292,224,109	251,187,187
Gross profit	66,410,790	44,382,708
Interest and miscellaneous income	381,884	685,963
Total income	66,792,674	45,068,671
Administrative, engineering, selling, advertising, service, and general expenses	25,656,703	20,657,928
Interest paid and accrued, and (in 1935) premium of $1,507,525 on debentures called, and (in 1933) additions to reserves	82,766	2,223,336
	25,739,469	22,881,264

Profit before provision for federal, state, and foreign income, excess profits and undistributed profits taxes...........................	41,053,204	22,187,406
Provision for federal, state, and foreign income, excess profits, and undistributed profits taxes...........	11,579,467	3,528,097
Net profit....................	$29,473,737	$18,659,309
Depreciation and amortization charged to cost of sales and expenses in amounts of............	$7,583,724	$13,656,520

4 Reo Motor Car Company

This company presents an interesting case somewhat different from the conditions encountered in the above companies. The break-even chart of this company is shown in Fig. 5. The general trend of total expense from 1916 to 1928 follows the full line drawn immediately below the 45-deg line of income. The expense points are somewhat scattered and four of them (for the years 1916, 1923, 1921, and 1929) fall wide of the trend. Next below the trend line of total expense we find the broken line of "cost of sales" (cost of manufacturing the goods sold). This trend of cost of sales is very uniform for the period from 1924 to 1934. Comparing the trend line of total expense with the trend line of cost of sales from 1924 to 1928 we find that as sales income increased, the administrative and selling expense increased at a greater rate, that is, the spread between the two lines increased as sales income increased. When sales declined in 1929 the cost of sales dropped consistently with income, but the administrative and selling expense in relation to income did not. In fact, the spread between total expense and cost of sales increased between 1927 and 1929 as the chart clearly shows.

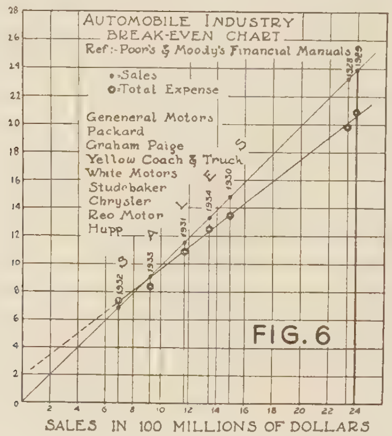

FIG. 6

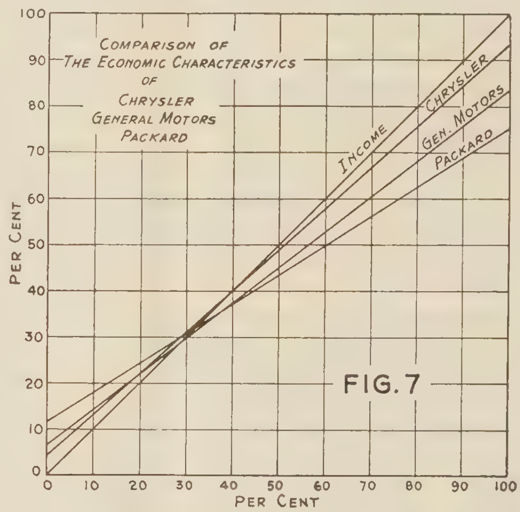

FIG. 7

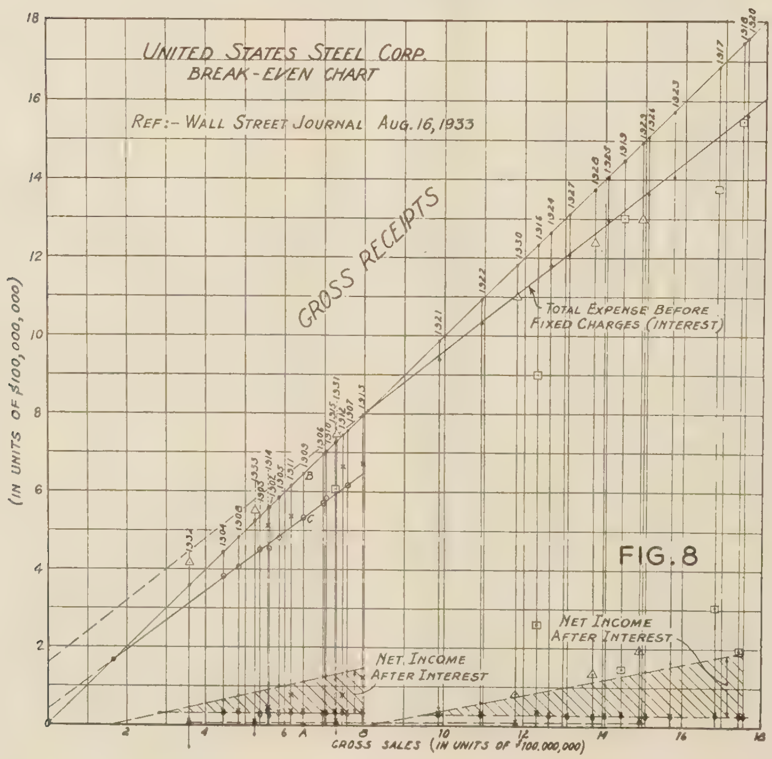

FIG. 8

As sales declined still further in 1930, the company ran into a loss. Further declines in sales as shown for 1931 and 1932, while accompanied by a drastic reduction of administrative and selling expenses, showed substantial losses. The cost of sales trend, however, followed the same line which it had in the earlier years. As sales increased in 1933 and 1934, still further reductions in the general overhead were brought about and losses were reduced, but the cost of sales returned along the same trend line which it had in earlier years. This company apparently did not have control of its total expenses particularly the general overhead, which the other companies previously considered appear to have had and while its cost-of-sales line showed a uniform relationship to sales income over a wide range of sales and for a considerable span of years, its administrative and sales expenses and hence the total expenses showed erratic behavior in relation to income.

5 Consolidated Break-Even Chart of Several Companies

The annual sales and annual total expenses of several automobile manufacturing companies were compiled and the results used to construct the break-even chart shown in Fig. 6. The companies were General Motors, Packard, Graham-Paige, Yellow Coach and Truck, White Motors, Studebaker, Chrysler, Reo, and Hupp. These represent a typical group, outside of the Ford Motor Co. This chart shows the following economic characteristics for the group for the period 1928 to 1934

Annual fixed expense point	=	$190,000,000
Variable cost factor	=	0.78
Equation of annual total expense	=	$190,000.000 + (78 per cent of sales)
Equation of annual profit	=	(22 per cent of sales) — $190,000,000
Break-even point	=	$862,000,000 annual sales

6 Comparison of Economic Characteristics of Several Companies

The break-even chart shows, among other things, the relation of total expense to income over a range of sales. The charts of the several automobile companies just examined show that they each differ from one another in both fixed and variable expenses in relation to income. Since, however, they also differ in productive capacity it is not possible to make a direct comparison of their break-even charts. In order that this may be done, each chart must be set up in terms of per cent of productive capacity or on other appropriate bases. The records do not show what the productive capacity of each company is and therefore this must be approximated by assuming that the maximum capacity is represented by the maximum sales.

Three companies will be compared on this basis: General Motors, Chrysler, and Packard. The maximum sales in each case were

General Motors	$1,504,400,000	1929
Packard	107,500,000	1929
Chrysler	517,000,000	1935

The ratios of the fixed costs to maximum sales and the variable cost factors are

	Fixed cost max sales per cent	Variable cost factor per cent
General Motors	7	76.5
Packard	12.1	63.2
Chrysler	4.8	89

The comparative break-even charts shown in Fig. 7 were constructed from these data. This graphic analysis shows that when each company is run at maximum capacity, the Chrysler Corporation has a profit of 6.2 cents for every dollar of income, the General Motors Corporation has 16.5 cents and Packard has 24.7 cents or approximately 4 times that of Chrysler and $1^1/_2$ times that of General Motors. It is interesting to note that the Packard Company has the highest fixed costs in proportion to maximum income and the lowest variable costs, while the Chrysler Corp. which has the lowest ratio of fixed costs to maximum sales has the highest variable costs.

The total assets of these companies at the time of their maximum sales were

General Motors	$1,324,889,000 in 1929
Packard	78,789,000 in 1929
Chrysler	151,133,000 in 1935

Accordingly, in these years General Motors showed a profit of approximately 19 cents per dollar of total assets, Packard showed 33.7 cents and Chrysler 21.2 cents.

B Steel

The economic characteristics of companies operating in this industry are illustrated by the records of operation of the largest company in the industry, The United States Steel Corp., and one of the smaller units, The Granite City Steel Co.

1 United States Steel Corporation

The records of gross receipts and total expenses before interest charges of this company from its formation in 1902 to 1933 are given in Table 1.

TABLE 1 UNITED STATES STEEL CORPORATION

Data from Crandall's Corporation Reports, Oct. 6, 1934
The Wall Street Journal, Aug. 16, 1933
(in $1000 units)

Year	Gross receipts	Total expense	Net earnings	Interest charges	Net income after interest charges
1902	560,510	453,685	106,825	22,034	84,791
1903	536,573	451,612	84,961	25,637	59,324
1904	444,405	382,570	61,835	30,091	31,744
1905	585,332	481,939	103,389	29,767	73,622
1906	696,757	570,649	126,108	29,401	96,707
1907	757,015	617,282	139,733	29,353	110,380
1908	482,308	405,701	76,607	31,264	45,343
1909	646,382	534,923	111,499	31,504	79,955
1910	703,961	583,395	128,566	30,630	89,936
1911	615,149	537,528	77,621	31,145	46,476
1912	745,506	665,632	79,874	32,569	47,305
1913	796,894	672,875	124,019	32,518	91,501
1914	858,415	513,772	44,643	32,322	12,321
1915	726,684	607,110	119,574	31,783	87,791
1916	1,231,474	900,524	260,950	31,026	299,924
1917	1,683,963	1,377,608	306,355	30,126	276,229
1918	1,744,312	1,548,228	196,084	29,822	166,262
1919	1,448,558	1,300,886	147,672	29,211	118,461
1920	1,755,477	1,563,754	191,723	28,514	163,209
1921	986,750	939,720	47,030	27,745	19,285
1922	1,092,698	1,032,958	59,740	27,492	32,248
1923	1,571,414	1,407,097	164,317	27,072	137,245
1924	1,263,711	1,179,905	83,806	26,343	57,463
1925	1,406,505	1,296,977	109,528	26,006	83,522
1926	1,508,076	1,365,942	142,134	25,515	116,619
1927	1,310,393	1,209,903	100,490	24,665	75,825
1928	1,374,443	1,239,184	135,259	23,788	111,471
1929	1,493,505	1,298,228	195,277	14,945	180,332
1930	1,180,935	1,099,455	81,480	5,640	75,840
1931	729,377	748,885	—19,508	5,470	—24,978
1932	357,202	416,875	—59,673	5,313	—64,986
1933	524,969	550,695	—25,726	5,165	—30,891

These data are plotted in Fig. 8. This chart shows four distinct eras in the expense history of the company. From its foundation in 1902 to the year 1910, the expenses followed a very regular trend in relation to gross receipts. This trend was

Avg annual total expense = $40,000,000 + (76 per cent of gross receipts)

The corresponding equation of net earnings was

Avg annual net earnings = (24 per cent of gross receipts) — $40,000,000

The break-even point before interest charges of the business during that era was approximately $166,000,000. The chart shows that the break-even point after interest charges was about $300,000,000. The company at that time had a heavy bonded indebtedness. The next era was for the four years of 1911 to 1914, the trend line for which is not drawn. Then followed the war

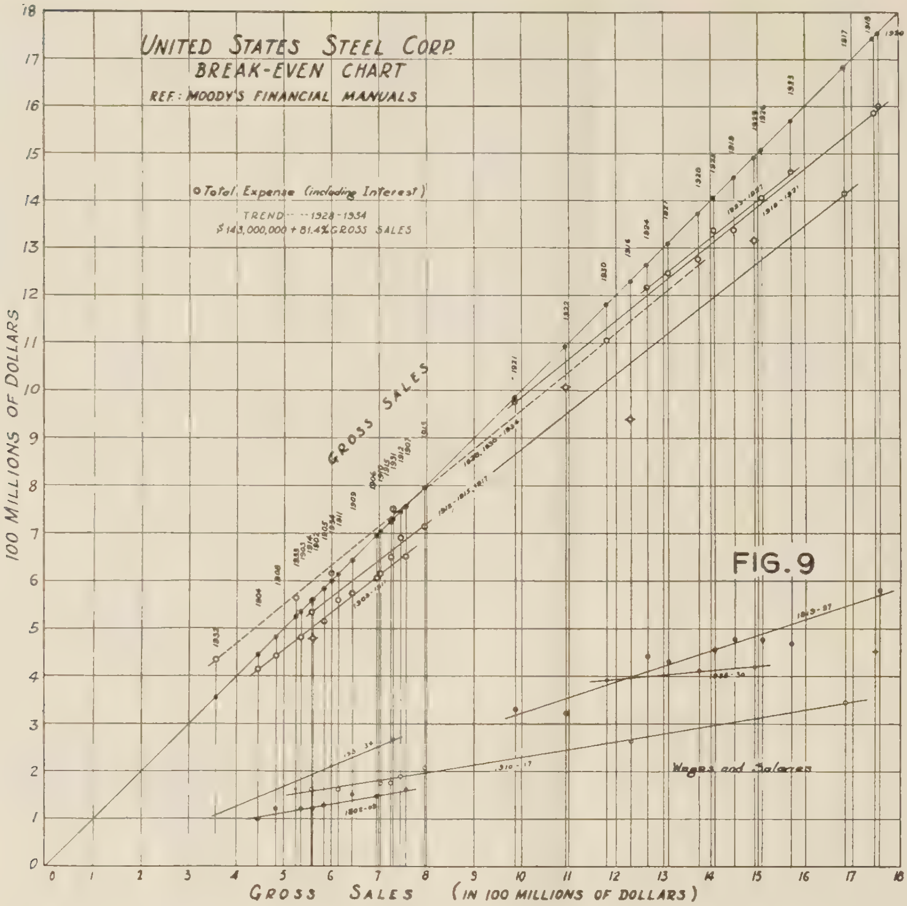

FIG. 9

years of 1915 to 1917 during which the company experienced the greatest earnings in its history in the years 1916 and 1917. During 1918 its total expense in relation to gross receipts became greater and initiated the trend of the next era. The fourth era included the largest output in the company's history when in 1920 its gross receipts were slightly over $1^3/_4$ billion dollars. For a period of ten years from 1918 to 1927 during which sales fluctuated widely, the trend of expense was

Avg annual total expense = $158,000,000 + (80 per cent of gross receipts)

The equation of profit for this era was

Avg annual net earnings = (20 per cent of gross receipts) — $158,000,000

The company now needed to have annual gross receipts of $790,000,000 to break even before interest charges. A comparison between the actual net earnings and those computed by the above equations is given in Table 2. It is interesting at this time to note that the conditions under which the company was operating during this era were such that it broke even at a point where it formerly, in this first era, made its maximum profit and that to make the same profit it formerly made at $800,000,000, gross receipts, it had to have annual gross receipts of approximately $1,550,000,000 or nearly twice as much. In view of the fact that its invested capital was also much greater, this change in the earnings characteristics of the company is very significant.

In 1928 and 1929 the spread between total expenses and gross receipts was increased, but in 1930 and 1931 it approached the trend of the post-war era. As sales continued to decline to the lowest in the history of the company in 1932 ($357,000,000) and then continued to rise in 1933 the expenses in relation to gross receipts followed below the earlier trend.

When the total expenses including interest charges are plotted against gross sales we find a series of trends as shown in Fig. 9. It will be seen from this chart that the addition of interest charges

TABLE 2 UNITED STATES STEEL CORPORATION NET-EARNINGS TRENDS

Symbol	Era	Period	Years	Equation
	First	1902–1910	9	$0.24x$ — $40,000,000
	Fourth	1918–1927	10	$0.20x$ — 158,000,000

Years	By equation	Actual	Difference	
First era

1922	60,539,600	59,740,000	− 799,600	
1923	156,282,800	164,317,000	+ 8,034,200	
1924	94,742,200	83,806,000	−10,936,200	
1925	123,301,000	109,528,000	−13,773,000	
1926	143,615,200	142,134,000	− 1,481,200	
1927	104,078,600	100,490,000	− 3,588,600	
Total	1,237,578,400	1,242,524,000	+ 494,560	
Average	123,757,840	124,252,400	+ 49,456	+0.4%

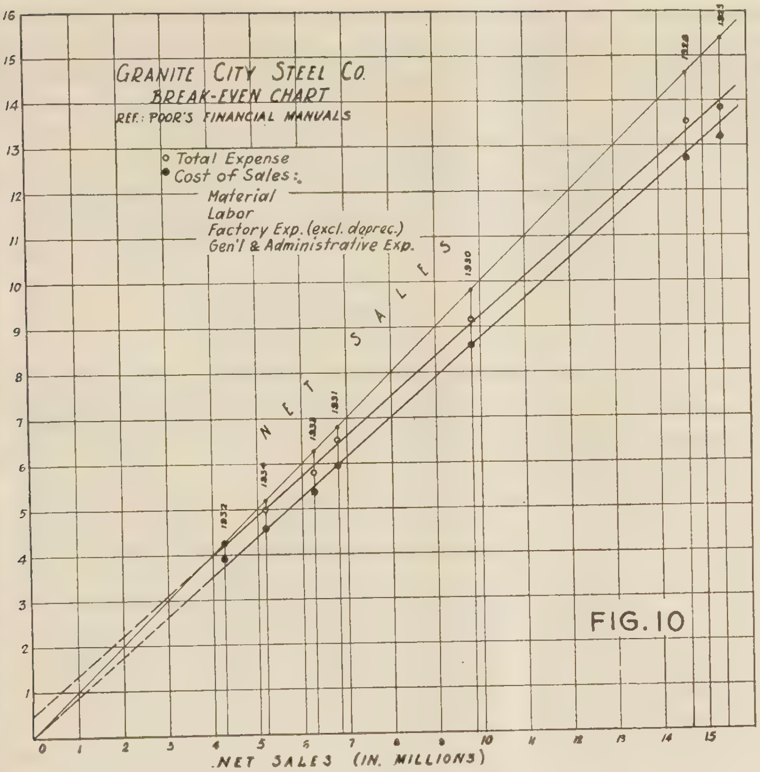

FIG. 10

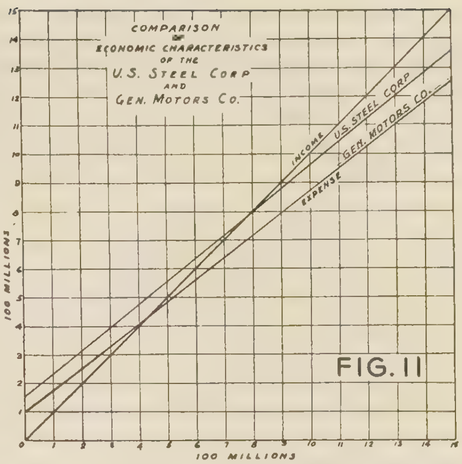

FIG. 11

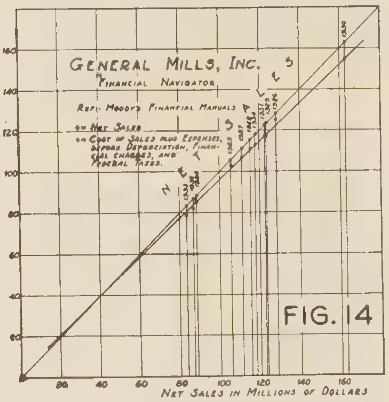

FIG. 14

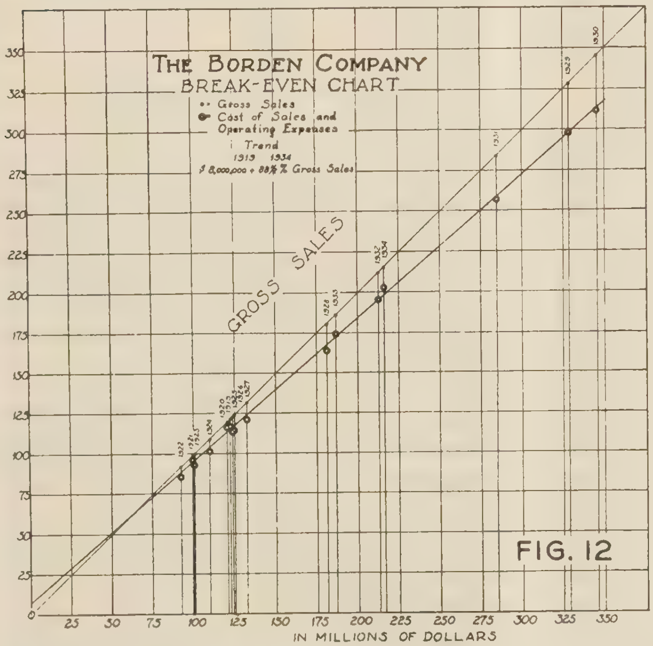

FIG. 12

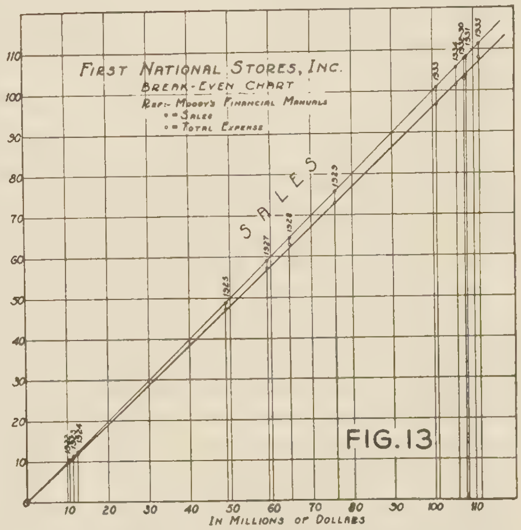

FIG. 13

establishes more distinctive trends. For example, from 1923 to 1927, the total expenses including interest charges had a trend above the 1918 to 1921 showing, with a distinct drop for the period 1928 to 1934 in which 1929 is not included. If the company should continue its operations along this trend it appears that it should have

Avg annual net income = (18.6 per cent of gross sales)—$143,000,000

This chart also shows how wages and salaries have varied throughout the years. Comparing the trend in wages and salaries for the period 1902 to 1909 with that for the period 1921 to 1934, it will be observed that wages and salaries account for a large portion of the difference in trends of total expenses for the periods 1903 to 1911 and 1928 to 1934.

2 The Granite City Steel Co.

This company in terms of maximum output is less than 1 per

cent the size of the United States Steel Corp. Its record of income and expense since 1929 is shown in Fig. 10. This chart shows both cost of sales and total expense in relation to net sales. The company has shown a profit all during the depression period and its trend of expense has been very consistent. This trend is

Avg annual total expense = \$500,000 + (87.5 per cent of net sales)

3 Comparison of U. S. Steel and General Motors Corporations

These two companies are approximately the same size as measured in terms of maximum sales. The maximum gross receipts of the United States Steel Corp. in 1920 were $1^3/_4$ billion dollars. The net sales of the General Motors Corp. in 1929 were $1^1/_2$ billion dollars. The relative income-expense trends of the two companies are compared in Fig. 11. This chart shows the superior position of the General Motors Corp. to the United States Steel Corp. in terms of earnings per dollar of income, and in the range of sales over which earnings are made. The chart does not show what is even more significant, and that is, that the United States Steel Corp. has approximately one billion dollars more capital than General Motors and hence the earnings in terms of invested capital are even more favorable to the General Motors Corp.

C Food Products

1 The Borden Company

The principal business of this company is the collection, processing and distribution of milk in the city of New York. It also produces and distributes ice cream and handles some dairy products. From 1919, when its business was slightly less than 125 million dollars annual sales, it grew to enjoy a volume of sales of slightly less than 350 million dollars in 1930. Since then its sales dropped to about 185 millions in 1933 from whence they rose to about 230 million dollars in 1935. During all these years, while the annual business increased and decreased substantially, its cost of sales and operating expenses followed a consistent general trend in relation to income, as shown in Fig. 12. The company shows a very low break-even point, approximately 20 per cent of maximum income, although this is before administrative expenses and financial charges which data were not available to us.

2 First National Stores

This company conducts a large chain of grocery stores and its business has grown from a little more than 10 million dollars sales in 1922 to over 110 million dollars in 1935. Throughout this entire period of time, its total expenses have been maintained at a fixed percentage of sales income, approximately 96.25 per cent as shown in Fig. 13. This means that for every dollar of sales, the company makes a profit of $3^3/_4$ cents. This company in common with many other chain groceries, seems to have a fixed cost point at zero. This does not mean that the company has no constant total expenses in its budget, but rather that as the company increased its operations, it controlled the increase of its rents and other fixed cost items in proportion to the increase in income.

3 General Mills, Inc.

This company owns and operates flour mills and distributes flour over a wide territory. The reports of its operations show costs of sales before depreciation, financial charges, and federal taxes for the period from 1925 to 1933 to have followed a straight-line trend in relation to net sales as shown in Fig. 14. Only in 1926 was there an appreciable increase in these costs while in 1932 and 1933 they were somewhat less than the general trend. The company has a very narrow spread between these expenses and the income and when the other costs are accounted for it probably has a very high break-even point.

4 The Great Atlantic & Pacific Tea Co.

This company operates one of the largest chains of grocery stores in the world. Its total expenses in relation to income, for a long period of years and over a wide range of sales, as shown in Fig. 15, have been uniformly 97.3 per cent. For every dollar of income therefore, the company averages a profit of 2.7 cents. This record has been maintained from 1924 when its sales were slightly more than 300 million dollars, to 1931 when sales were over 1 billion, 60 million dollars. When sales declined in 1932, 1933, and 1934, its total expenses continued to follow the same trend.

D An Office Building

1 Equitable Office Building Corporation

The business of owning and operating an office building for profit is a wholly different affair from the production and merchandising of manufactured goods or the distribution of groceries, yet it also shows very definite trends of expense in relation to income.

The Equitable Office Building Corp. owns and operates one of the largest office buildings in the financial district of New York City. In this type of business enterprise the constant total costs are very high and the variable total costs are comparatively low. The record of incomes and expenses for this business for the years 1924 to 1935 are plotted as shown in Fig. 16 from which it is found that the trend of total expense in relation to income is

Annual total expense = \$2,300,000 + (26 per cent of income)

and the equation of profit is

Avg annual profit = (74 per cent of income)—\$2,300,000

while the break-even point is

Annual break-even point = \$3,100,000

E Electrical Manufacturers

1 The General Electric Company

This company is one of the largest manufacturers of electrical machinery and allied equipment in the world. In 1910 its annual sales were approximately 70 million dollars and in 1929 they were over 400 million dollars, or nearly six times as great. Since 1929, annual sales receded to about 135 million in 1933, from whence they rose to 233 million for the year closing June 30, 1936. Throughout this whole period of years a wide range of annual sales, the company has shown a most remarkable control of total expenses in relation to income. This is clearly indicated in Fig. 17 which shows the relation of total expenses to net sales of this company from 1910 to 1932. There appear to be four general eras on this chart for two of which, the first and third eras, are given the equations of profit trend. The first era is from 1910 to 1917 during which the trend in total expense was

Annual total expenses = \$3,000,000 + (86.33 per cent of net sales)

The second era was from 1918 to 1921 for which no trend is drawn. The third era was from 1922 to 1927 during which the trend of total expenses was

Annual total expenses = \$9,000,000 + (86.7 per cent of net sales)

The fourth era from 1929 to date shows that during the decline in sales from 1929 to 1933, expenses in relation to sales were slightly greater than in the third era while sales were rising, but as sales began to rise again there seems to be a tendency to follow the expense trend of the third era. It seems to be a fair probability that with increasing business this company should follow the trend of total expenses which it had from 1922 to 1929. In this event its break-even point would be approximately

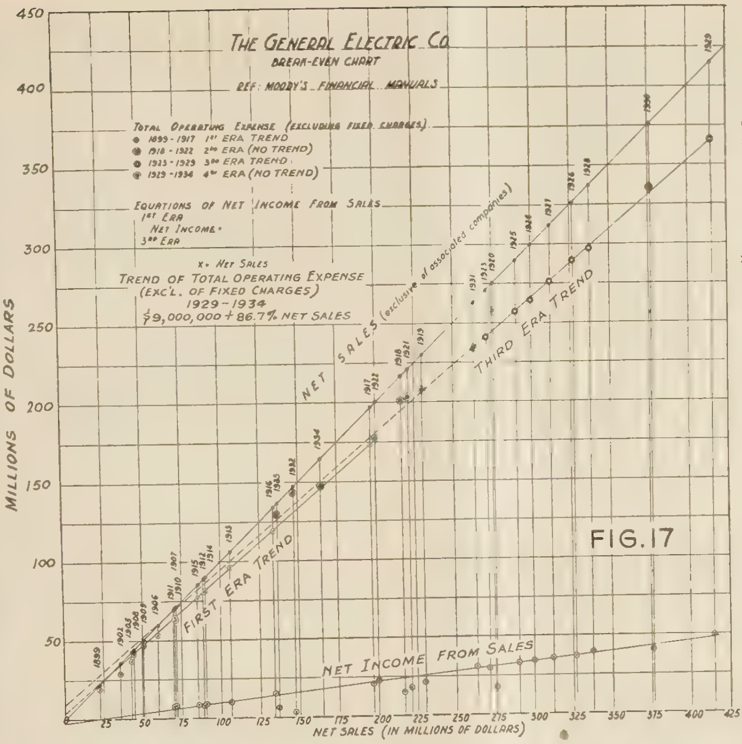

FIG. 17

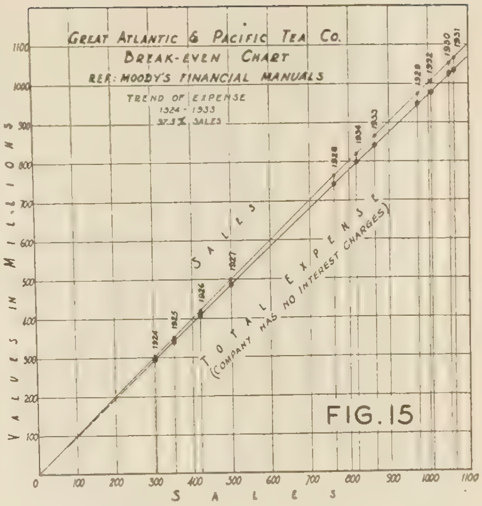

FIG. 15

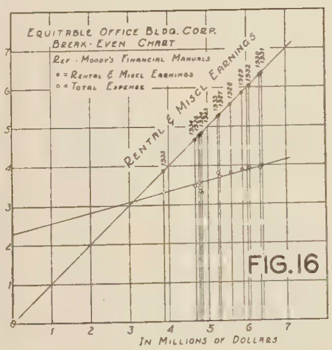

FIG. 16

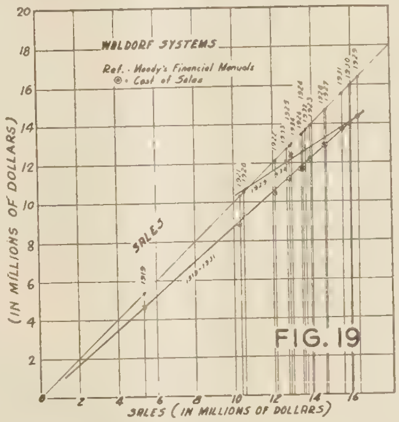

FIG. 19

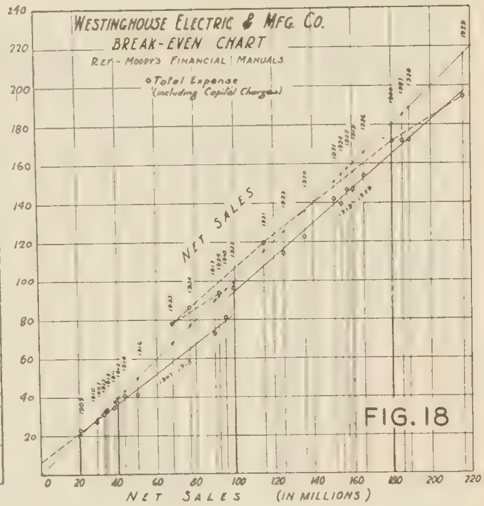

FIG. 18

$67,600,000 annual sales or about 15 per cent of maximum sales of 1929.

In support of this estimate of probable expense trend, we present the following comparisons of actual total expenses from sales for the years closing June 30, 1935 and 1936, and the computed expenses

	1935	1936
12 months billing	$178,360,497	$233,460,547
Costs and expenses	165,440,573	210,160,307
Computed from equation of trend	163,630,000	211,410,000
Difference	1,810,573	1,249,693
Per cent difference	1.1	0.6

The total average costs and expenses for the two years is $187,800,000 and that computed for the average sales for the two years is $187,520,000 or a difference of 0.17 per cent.

Since the General Electric Co. derives a large income from other sources than from the sale of the products it manufactures, the total net income of the company is frequently greater than the net income from sales alone. For example, in the year closing June 30, 1936, the company reported net income from sales amounting to $23,300,240 and other income, less charges of $9,594,427, bringing its net income up to $32,894,667. Only the net income from sales is compared with the total expense in the above analysis.

2 Westinghouse Electric and Manufacturing Company

This well-known company manufactures and distributes about the same kind of products as the General Electric Company. An analysis of its incomes and expenses as reported in Moody's Financial Manuals from 1907 to 1934, and plotted in Fig. 18 shows three distinct phases in its earnings history. From 1907 to 1918 its annual sales range from over 20 million dollars in 1909 to about 96 million in 1918. During this entire period, its annual total expenses in relation to annual net sales followed the general trend

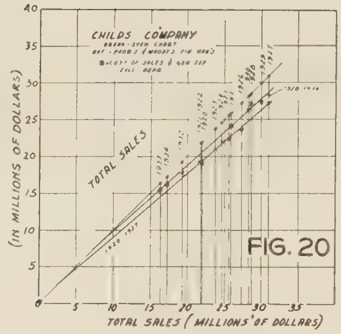

FIG. 20

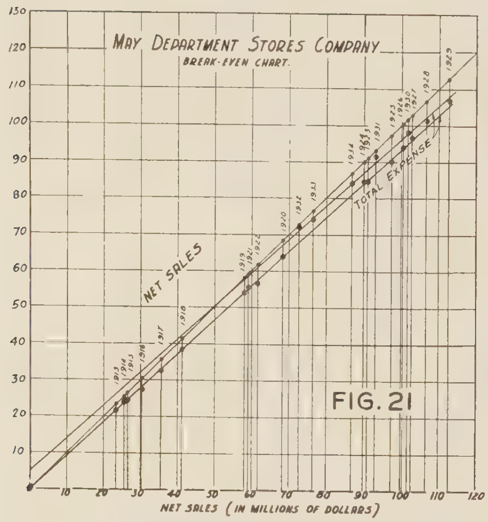

FIG. 21

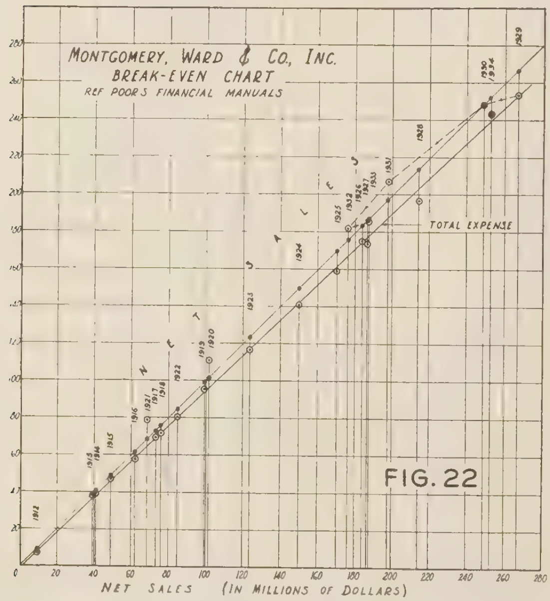

FIG. 22

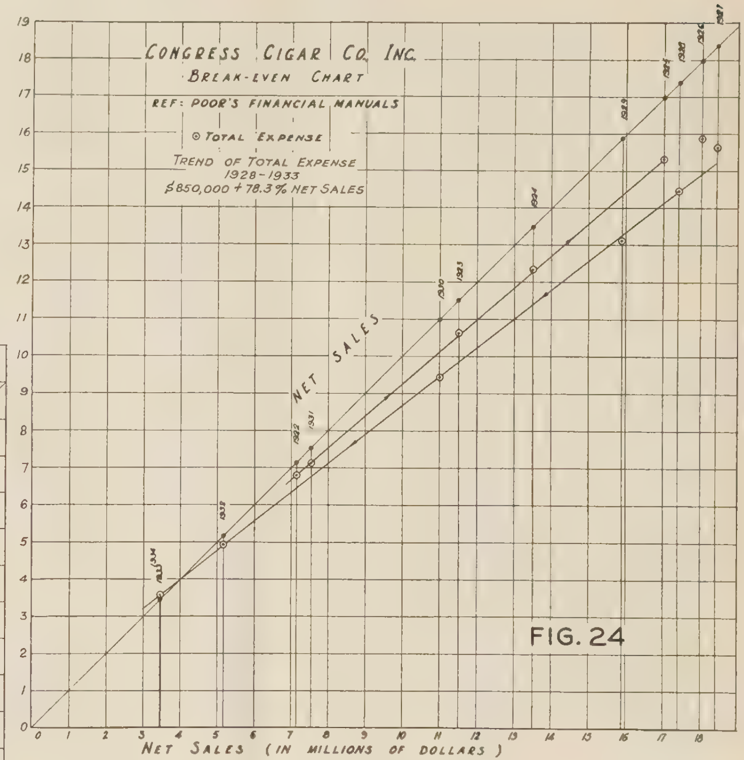

FIG. 24

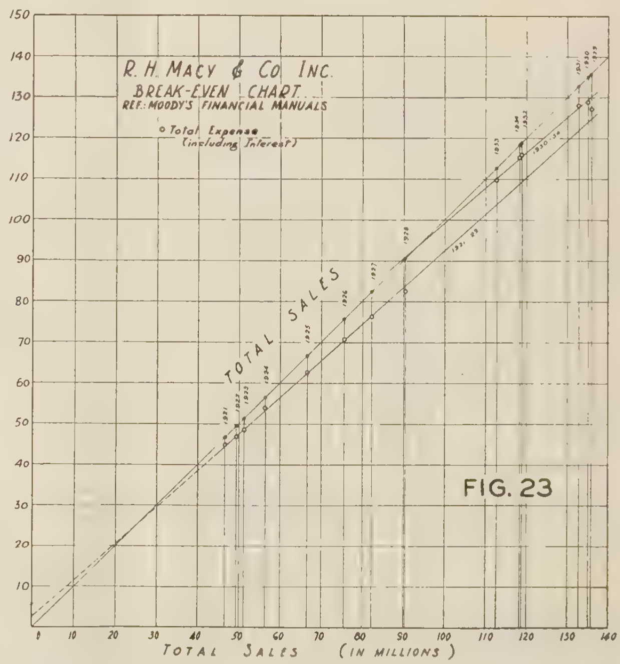

FIG. 23

Annual total expense = \$6,000,000 + (78 per cent of net sales)

and it broke even at annual net sales of \$27,000,000. From 1919 to 1929 its business increased materially and ranged from slightly less than 100 million dollars annual net sales in 1922 to about 216 million in 1929. During this period it altered the relation between the annual total expenses to annual net sales, for which the trend was

Annual total expense = \$8,000,000 + (87 per cent of net sales)

Its break-even point was also raised to approximately \$61,000,000. It is interesting to observe that whereas its equation of profits from 1907 to 1918 was

Avg annual profits = (20 per cent of net sales)—$6,000,000

after its expansion, its profits from 1919 to 1929 followed the general trend

Avg annual profits = (13 per cent of net sales)—$8,000,000

Accordingly, should the company have had, for example, annual net sales of 100 million dollars during any year between 1907 and 1918, the probabilities are that it would have had a profit of approximately (20 per cent of $100,000,000)—$6,000,000 or $14,000,000. After its expansion, however, if it were to have an annual profit of $14,000,000 it would have had to have annual sales of

$14,000,000 = (13 per cent of net sales) — $8,000,000, or approximately $170,000,000

Thus the company after its sales expanded, found that its margin of profit had narrowed and that it had to do about 70 per cent more business than its previous maximum capacity to make the same annual profit as before.

F Restaurants

1 Waldorf System, Inc.

This company operates a chain of restaurants. In 1919 its annual sales were over $5^1/_4$ million dollars and 10 years later it did an annual business of over 16 million dollars, thus increasing its output over three times. From 1919 to 1931 its cost of sales followed a very consistent trend in relation to income as shown in Fig. 19. The annual cost of sales during these years was 87 per cent of the income from sales. Beginning with 1932 however, it departed materially from this trend. In fact, the new trend may be associated with the years 1929 to 1934. It is not always apparent in cases like this where two trends merge, just where the new trend begins in time. It is obvious however, that as the business declined during the depression, the company did not adjust its cost of sales to income.

2 Childs Company

This famous chain of restaurants is approximately twice as large as the Waldorf System, measured in terms of the maximum income received in 1929, but its income declined more rapidly during the depression, from 30 million dollars in 1929 to about $16^1/_4$ million in 1933, a drop of 45 per cent, while the Waldorf System dropped only 22.5 per cent.

The relation of cost of sales and general expense, excluding depreciation, to total sales, for this company, is shown in Fig. 20. From 1920 to 1927 the trend of these expenses was

Annual expenses = $500,000 + (86 per cent of total sales)

During the depression when sales declined it followed a new trend of

Annual expenses = $1,000,000 + (89 per cent of total sales)

Thus it increased its annual fixed costs by $500,000 and its variable expenses by 3 per cent.

G Department Stores

There are two general types of department stores considered in this survey. The one type, represented by the May Department Stores Company does a standard retail business, and the other type represented by Montgomery Ward & Company, Inc. does both a mail-order and standard retail business, although the establishment of its retail stores is of recent origin; the company originally doing a mail-order business exclusively.

1 May Department Stores Company

The relation between income and total expense for this company from 1913 to 1934 is shown in Fig. 21. From 1913 to 1929 the annual net sales of this company grew from approximately 25 million dollars to over 111 million dollars. During this entire period of 17 years it maintained average total expenses at approximately 93.5 per cent of net sales, although in 1928 and 1929 its expenses exceeded this proportion. In fact, from 1928 to 1934 it shows a distinctly new trend of

Avg annual total expenses = $5,000,000 + (91 per cent of net sales)

2 Montgomery Ward & Company, Inc.

This company experienced a very rapid growth in business from 1912 to 1929 as shown in Fig. 22. Its sales in 1912 were less than 10 million dollars, but in 1929 they reached over 266 million dollars. Its total expenses during this period of growth followed closely the trend of 95 per cent of net sales. When sales began to decline in 1930, 1931, and 1932, the company apparently did not adjust its expenses to meet the declining sales income and consequently suffered losses in these years. In 1933 however, it began to make the necessary adjustments in its expenses so that by 1934 its expenses approached appreciably the old trend. The behavior of the expense line in relation to income shown by this company is typical of those of many businesses during the depression. It may be caused by a reduction in the unit selling price of the merchandise, or the failure to reduce expenses as sales decline, or to both situations.

3 R. H. Macy & Company, Inc.

This company operates one of the largest stores in New York City. The record of its total expenses to total sales shown in Fig. 23 indicates that from 1921 when sales were approximately $46^1/_2$ million dollars, to 1929 when they were about 136 million, the trend of expense was

Avg annual total expense = $2,500,000 + (90 per cent of total sales)

The greatest departure from this trend was in 1929 in which year the company began to experience a decline in its profit margin. From 1930 to 1934 during a period of sales decline with a slight rebound in 1934, a new trend in expense appears, which is

Avg annual total expense = $13,000,000 + (86.3 per cent of total sales)

If this trend is characteristic of the company's future operations, it appears that it must now do an annual business of about 95 million dollars to break even.

H Miscellaneous Businesses

1 Congress Cigar Company, Inc.

The earnings history of this business for the period 1922 to 1934 is shown in Fig. 24. Doing a business of more than 7 million dollars a year in 1922 the company in three years increased its annual sales to 17 million dollars. During this period, total expenses were maintained at a uniform rate with sales. With slight increases in sales in 1926 and 1927 the company decreased expenses and when sales took a downward trend in 1928, the company materially improved its margin of profit. In 1933 and 1934 sales dropped to almost $3^1/_2$ million dollars annually. During the entire period of decline the total expenses were controlled to follow the trend

Avg annual total expenses = $850,000 + (78.3 per cent of net sales)

The greater spread between total expenses and net sales during the depression period shown by this company is in sharp contrast to the experiences of many other businesses during the same period, as for example, the case which follows.

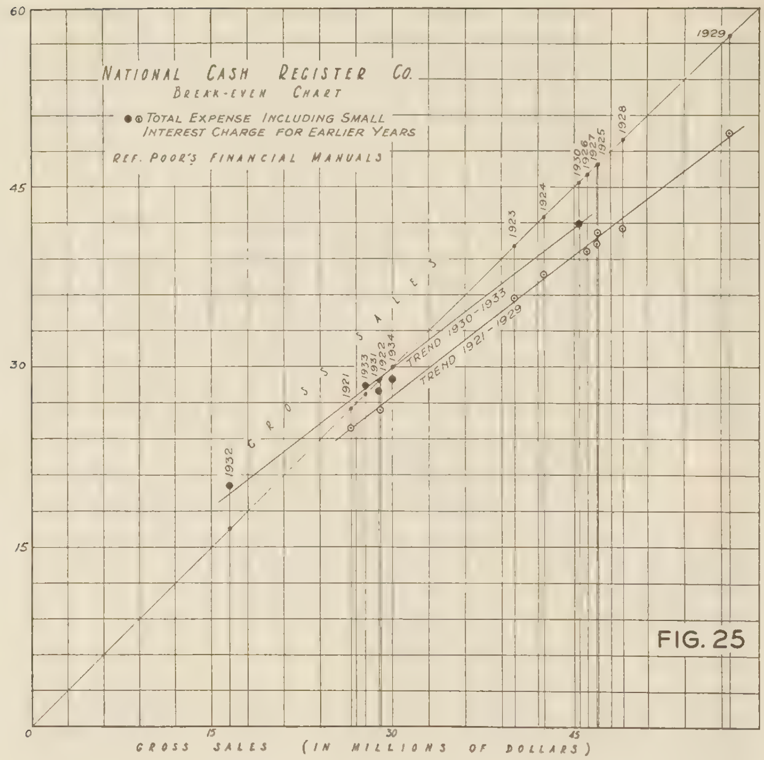

FIG. 25

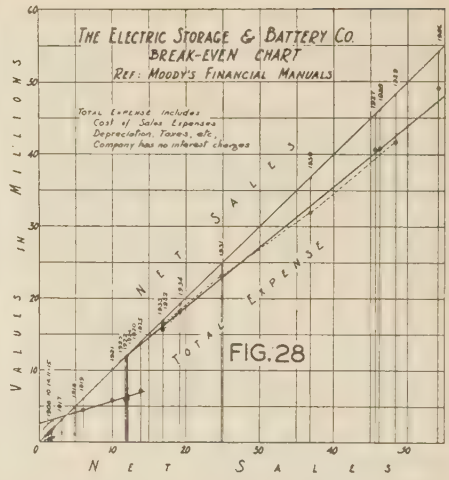

FIG. 28

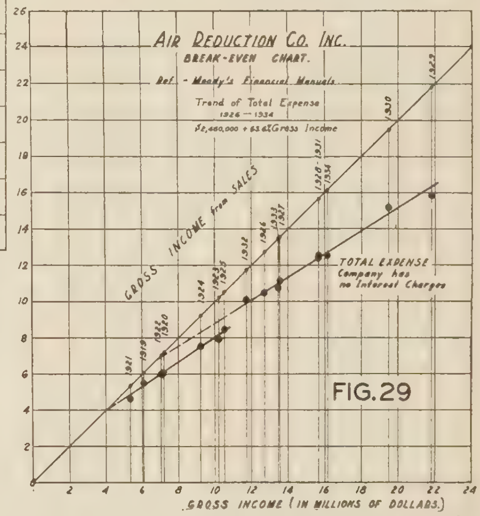

FIG. 29

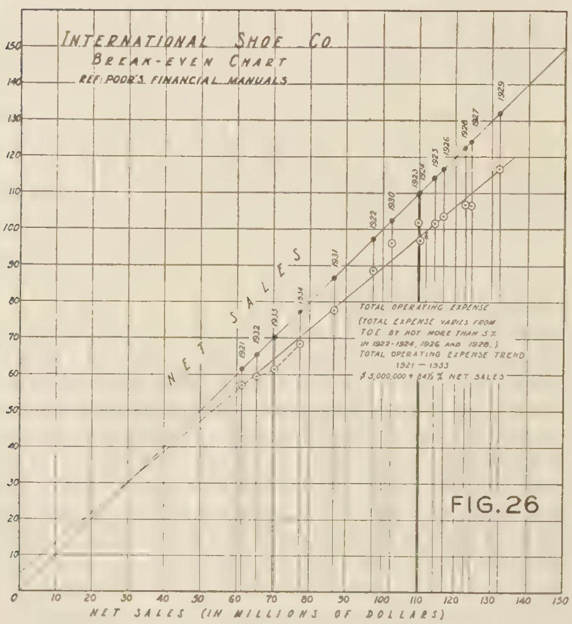

FIG. 26

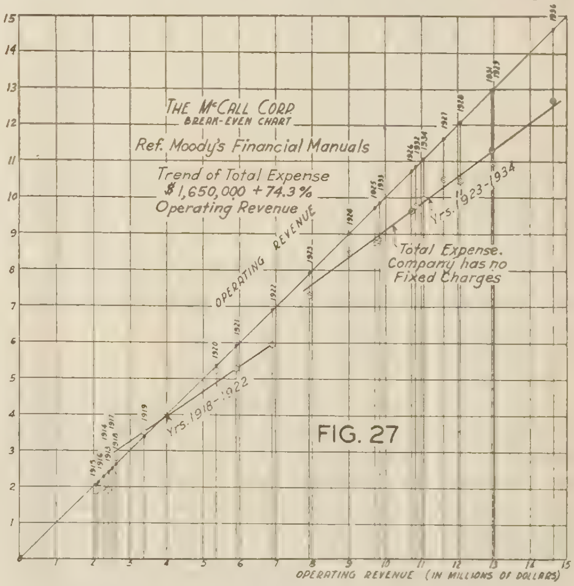

FIG. 27

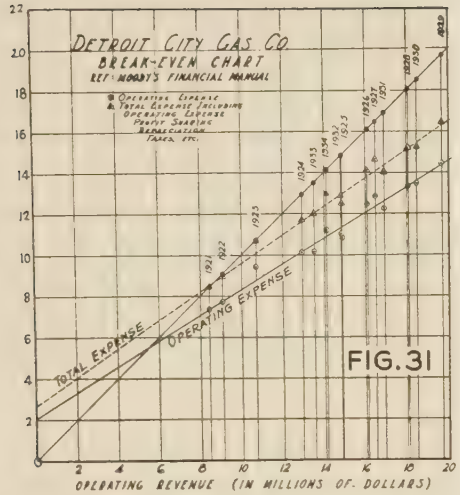

FIG. 31

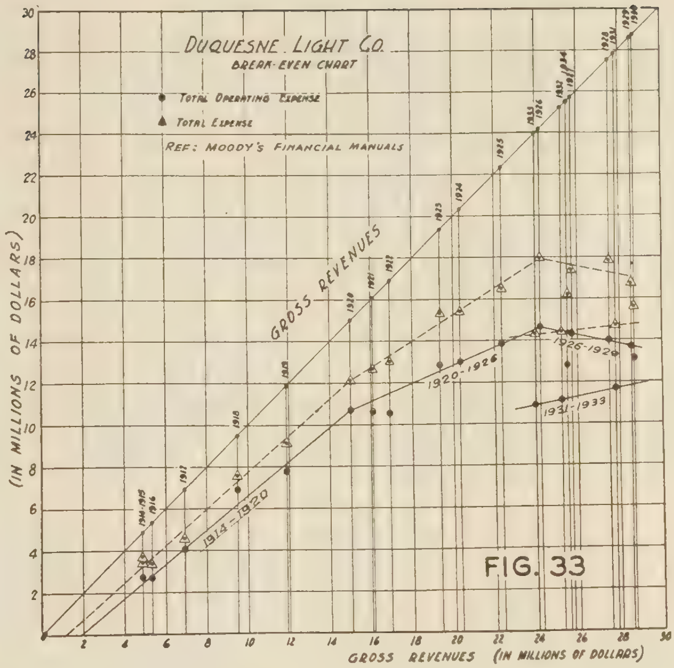

FIG. 33

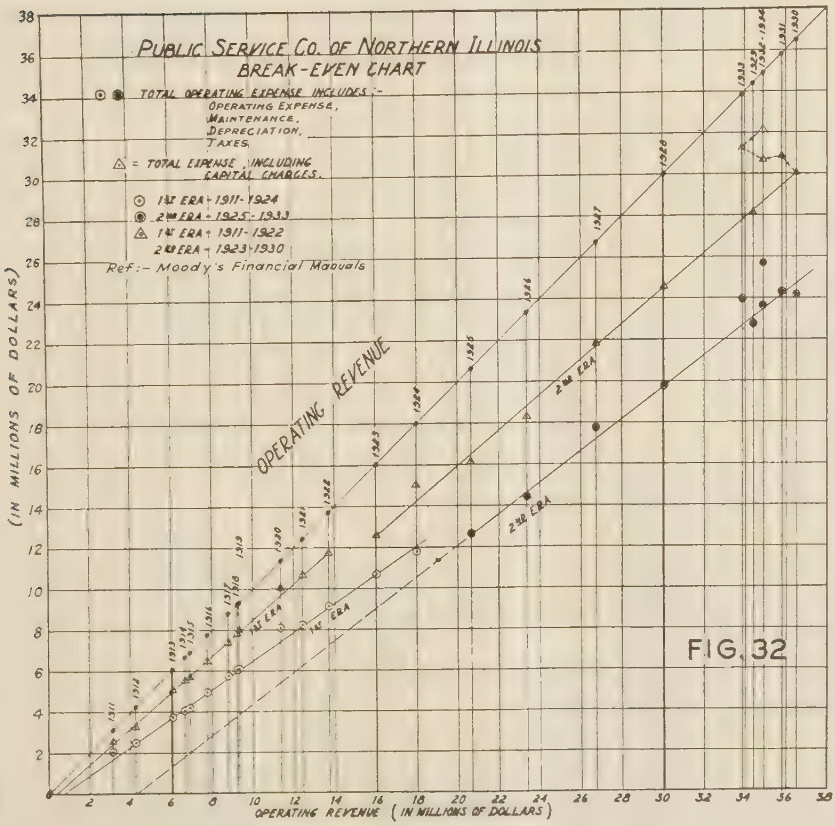

FIG. 32

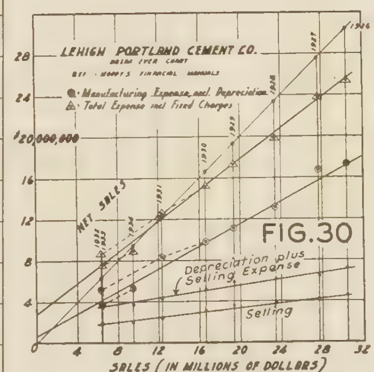

FIG. 30

2 National Cash Register Co.

As indicated in Fig. 25, this company shows two distinct trends of total expense to gross sales since 1921. Beginning with that year and extending to 1929 during which period its sales increased from less than 27 million dollars per year to over 48 million per year, it maintained an expense trend of

Avg annual total expense = \$4,000,000 + (78.33 per cent of gross sales)

In 1930 its sales dropped 21 per cent from the 1929 peak and its expense also followed a new trend for the four-year period 1930 to 1933. This trend was

Avg annual total expense = \$6,600,000 + (78 per cent of gross sales)

In 1931 however, the annual total expenses dropped below this trend, and again in 1934. Since this chart was constructed, the company reported its sales and net profits for the 12-month periods closing June 30, 1935 and 1936, in the New York Times of July 24, 1936. This report shows

	1935	1936
Sales	\$31,351,807	\$38,554,471
Net profit	810,597	1,981,509
Total expenses	30,541,210	36,572,962

According to the foregoing equation, the average annual total expense for the years should be for 1935, \$31,150,000; and 1936, \$36,600,000. It appears therefore, that the company is following closely the trend of total expense which was predicted in 1934.

3 International Shoe Co.

The reports of this company from 1921 to 1934 for annual total operating expenses in relation to annual net sales are recorded in Fig. 26. As this chart shows, the trend of expense is quite uniform for the entire period under review with only the expenses for the years 1923, 1927, 1930, and 1933 materially out of line. The general trend is

Avg annual operating expense = \$5,000,000 + (84.5 per cent of net sales)

The company has a very low break-even point, approximately at \$32,000,000 annual net sales, which is about 40 per cent of its 1929 output.

4 McCall Corporation

This company shows a rather unorganized relationship of total expense to operating revenue for the years 1913 to 1918 when its annual operating revenue fluctuated between 2 and $2^1/_2$ million dollars. As indicated in Fig. 27, with a rapid expansion of sales after 1918, there was a more definite trend of expense for the next four years when operating revenue rose to less than 7 million dollars for the year 1922. As income continued to rise from less than 8 million dollars in 1923 to over $14^1/_2$ million in 1930, there was developed a new and more uniform trend in expenses which also held during the decline in income to less than 10 million dollars in 1933 and its subsequent rise to over 11 million dollars in 1934. This trend of total expense which has persisted for 12 years is

Avg annual total expense = \$1,650,000 + (74.3 per cent of operating revenue)

This company may therefore be expected to break even at an annual operating revenue of about 64 million dollars which is approximately 44 per cent of the 1930 revenue.

5 The Electric Storage Battery Company

This company shows a rather interesting series of developments as shown in Fig. 28. From 1908 to 1918 the company did a comparatively small volume of business. In 1919 its income increased about 25 per cent over 1918, but its expenses increased about $4^1/_2$ times. From 1919 to 1925 the company more than doubled its sales and followed a new expense trend. Accordingly, as the chart shows, when it had net sales of 10 million dollars in 1921 it made only about the same profit as it did in 1918 when its sales were less than half this amount. In 1926 the company's sales increased to about 54 million dollars compared to approximately 14 million in 1925, but its profits were only about 75 per cent of those in 1925. Its total assets however, did not increase being approximately $44^1/_2$ million dollars in both years, therefore there was not occasion for higher fixed costs due to investments in plant and equipment. This was the peak in sales for this company. They dropped in 1927, regained slightly in 1928 and 1929, and then declined to less than 17 million dollars in 1932 and 1933. The trend of total expenses for the period 1926 to 1934 is

Avg annual total expense = \$2,000,000 + (84 per cent of net sales)

On the basis of this trend the company breaks even at annual net sales of \$12,500,000. It is interesting to note that for the four years 1920, 1922, 1923, and 1924, the company's sales were approximately this amount each year and at that time the profits were about 6 million dollars each year.

6 Air Reduction Company, Inc.

For the period 1926 to 1934 the total expenses of this company followed a very definite and uniform trend in relation to gross income from sales. As shown in Fig. 29 this trend is

Avg annual total expense = \$2,450,000 + (63.6 per cent gross income)

According to this trend the company should break even at about \$6,750,000.

7 Lehigh Portland Cement Company

This company did its maximum business in 1926 when its sales were over 30 million dollars. Since then, in common with other companies in the same industry, its sales fell rapidly. In 1932 they were only 21 per cent of what they were in 1926. However in this entire period, its expenses followed a generally uniform relation to income, as shown in Fig. 30. This chart shows not only the trend of total expense, with sales, but also the manufacturing expense and selling expense. It is not at all unlikely that this company will follow the expense trends shown on the chart as its sales increase in time. In that event, the trend of expenses will be

Avg annual total expense = \$2,800,000 + (75 per cent of net sales)
Avg annual manufacturing expense = \$600,000 + (55 per cent of net sales)
Avg annual selling expense = \$900,000 + (11.5 per cent of net sales)

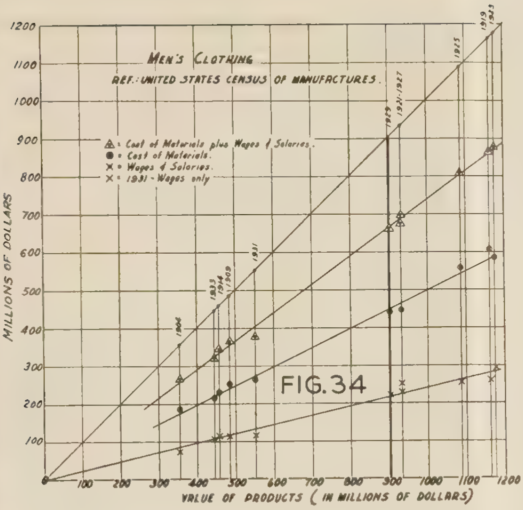
Its break-even point should be at about \$11,200,000 annual net sales.

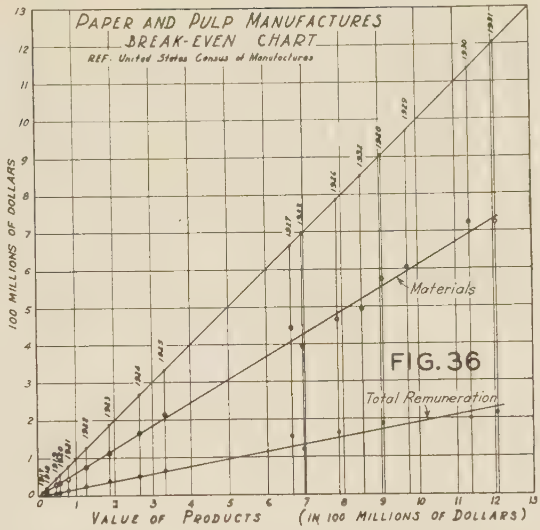
I The Utilities

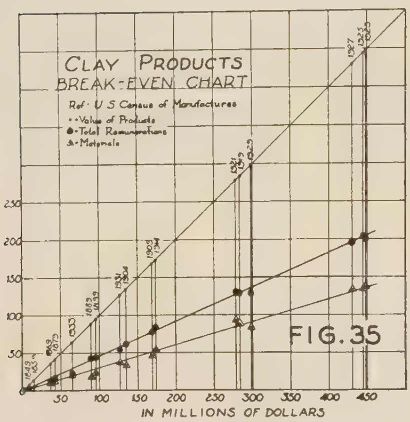
This group of industries differs from the manufacturing and merchandising businesses in many important particulars, and yet all show the same type of relationship between total expenses and income.

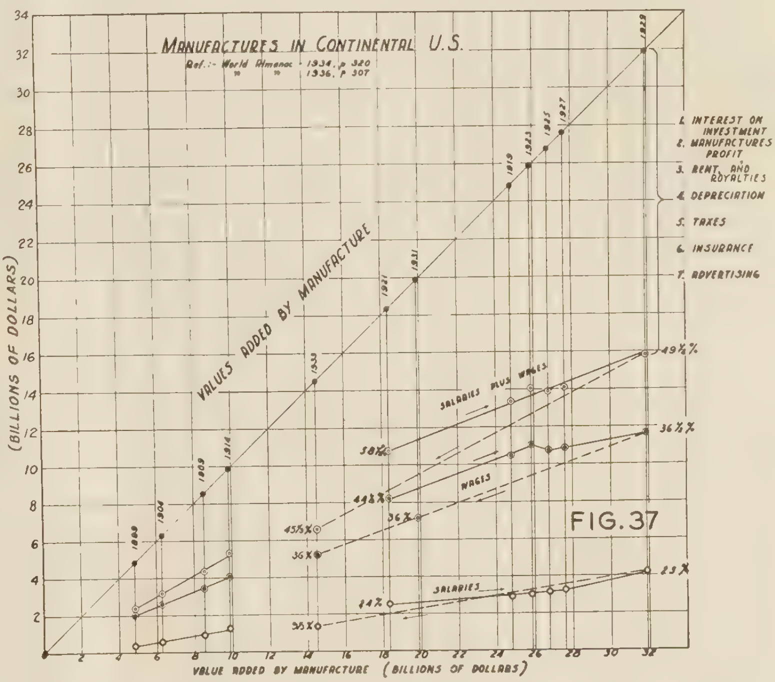
1 Detroit City Gas Company

The records of income and expense of this company from 1921 to 1934 are plotted in Fig. 31. This chart shows









Avg annual operating expense = \$2,000,000 + (62.6 per cent of operating revenue), and

Avg annual total expense = \$2,650,000 + (59.25 per cent of operating revenue), from which we find

Avg annual net earnings = (40.75 per cent of operating revenue)—\$2,650,000

From 1924 to 1933 the total assets of this company have increased from 40 million dollars to 72 million dollars. Accordingly while the net earnings in 1924 and in 1933 follow the same trend line as indicated in the chart, that is, the profit per dollar of operating revenue follows the same general relationship in 1933 as in 1924, in terms of invested capital, the company was in a less favorable position in 1933 than in 1924.

3 Public Service Company of Northern Illinois

The operations of this company in terms of income and expense from 1911 to 1934 are recorded in Fig. 32. Both total operating expenses and total expenses including capital charges are shown in relation to operating revenue. From 1911 to 1922 while the company's annual revenue increased from about \$3,000,000 to almost \$14,000,000 the increase in expenses with revenue was quite uniform. Operating expenses continued their trend in 1923–1924 but capital charges in 1923 were reduced while in 1924 they appeared again in the same trend. From 1925 to 1930 the company's annual revenue increased from over 20 million dollars to over 36 million dollars and both operating expenses and total expenses followed new trends. The spread between revenue and expenses increased during this period. From 1931 to 1934 revenue declined and while operating expenses declined along the trend line for the year 1931 total expenses rose sharply after which both operating and total expenses continued to increase without much change in revenue. In 1929 the total

assets of the company were 190 million dollars while in 1933 they were over 227 million.

3 Duquesne Light Company

The records of this company plotted in Fig. 33 show how a company may alter its economic characteristics in time. From 1914 to 1920 both operating expense and total expense follow fairly consistent trends with respect to gross revenues. After 1920 and up to 1926, the company increased its business but with a much greater spread between revenue and expenses. We have no history of operations of this company but since it is not likely that an increase in rates is responsible for this change the probabilities are that it brought about marked economies in operating conditions. After 1926 and up to and including 1929 the company effected a very marked reduction in operating expenses and continued these reductions during 1931 to 1933 while gross revenues declined. The fact that operating expenses increased materially in 1934 over the record of 1931–1933 can only be explained by an examination of the details of operating expense which are not available.

H Whole Industries

1 Men's Clothing

The production of this industry from 1904 to 1933 is shown in Fig. 34. It is interesting to observe that production in terms of dollars reached its peak in this industry in 1923 since when it has declined to almost $^1/_3$ of its maximum value. In this entire period of 30 years the average annual costs are

Wages and salaries	=	24 per cent value of product
Materials	=	50 per cent value of product

2 Clay Products

This industry also produced its maximum value of products in 1923 since when it declined in 1933 to about one ninth of its maximum. From 1929 to 1933 materials cost in relation to value of product has followed the general trend.

Average annual material cost = 30 per cent of value of product

and the trend in total remuneration has been, for 1889 to 1929

Average annual remuneration = 46 per cent of value of product

From 1929 to 1931 it fell to 43 per cent while in 1933 it fell to about 36 per cent. The records of this industry are shown in Fig. 35.

3 Pulp and Paper Manufacture

In terms of value of products this industry has had a remarkable growth since 1917, as shown in Fig. 36. As a distributor of wages and salaries it does not rank high, the general trend being

Average annual remuneration = 19 per cent of value of products

The reason for the low relative remuneration appears in the high cost of materials which is

Average annual materials cost = 61 per cent value of product

4 Manufactures in Continental United States

The value of the products manufactured in the United States together with materials, wage, and salary costs from 1899 to 1933 are shown in Fig. 37. Before 1929 the cost of materials averaged 58 per cent of the value of the products. From 1929 to 1933 the annual value of products fell from over 70 billion dollars to over 31 billion and the average cost of materials was 53 per cent during that period. With the exception of 1921, the average wage plus salaries was close to 22 per cent of the value of the products, both before and during the depression.

Modern Locomotive and Axle-Testing Equipment

By T. V. BUCKWALTER,[1] O. J. HORGER,[2] and W. C. SANDERS,[3] CANTON, OHIO

This paper shows how improvements have been made in the running and driving gear of existing and new steam locomotives to permit their operation at much higher speeds than is the usual practice today in both freight and passenger service. Means of obtaining these improvements are described whereby (*a*) the reciprocating parts are reduced in weight up to 1072 lb or 52 per cent, (*b*) the rotating parts on the main driving wheel are also reduced in weight up to 300 lb or 19 per cent, and (*c*) roller bearings are used on all axles and crankpins. As a result of such improvements, the dynamic augment on the rail and shaking forces on the locomotive and track structure at a given speed are reduced. The extent of this reduction is such that a speed increase of at least 35 mph above the diameter speed may be permitted without increasing the dynamic augment on the rails above its original value.

A program and facilities are described for the fatigue testing of full-size driver-axle assemblies with wheel-seat diameters of $11^1/_2$ in. Preliminary results indicate that valuable contributions will be forthcoming as to the influence of various designs, steels, and heat-treatments upon the axle fatigue strength.

The factors of unsprung weight and axle rigidity are not now considered in calculations of axle stresses. These factors influence the impact stresses in axles at prevailing high speeds and, to minimize the detrimental effect of such stresses, it is recommended that greater flexibility be designed in the axle by decreasing the present ratio of the axle diameter in the portion between the wheels to the diameter of the wheel seat.

High-Speed Operation of Steam Locomotives

The steam locomotive represents the lowest first cost per horsepower of motive-power units, and this fact in addition to its reliability and versatility of power has made difficult its displacement by other forms of motive power. Lately, however, competition is requiring design modifications which are not in general use today if the steam locomotive is to meet the operating requirements at the ever-increasing high speeds in both freight and passenger service.

This paper discusses the development and research problems involved in such design modifications, and deals with the mechanical equipment of the steam locomotive. The general objects of such improvements for high-speed operation are to obtain (*a*) reduced dynamic augment on the rails due to rotating and reciprocating parts so that it will not be detrimental to the existing track structure; (*b*) improved movement of the locomotive over the track by reducing nosing and fore-and-aft vibrations, thereby reducing the forces and maintenance costs on locomotive parts and track structure; (*c*) increased availability; (*d*) reduced operating maintenance cost; (*e*) greater acceleration; (*f*) increased speeds; and (*g*) increased tractive effort.

The Timken Roller Bearing Company has been dealing for years with the problems of obtaining these desired improvements in operating characteristics. Cooperation of various railroads in this development work has resulted in modifications in locomotive design incorporating the application of (*a*) lightweight reciprocating parts, including the piston, piston rod, and crosshead assembly; (*b*) lightweight main and side rods; (*c*) roller-bearing crosshead pins, main pins, side pins; (*d*) roller-bearing-equipped driver, trailer, engine- and tender-truck axles.

The beneficial results effected in locomotive operation through the application of Timken bearings to all axles are generally recognized. This is apparent from the fact that very few locomotives are being built or rebuilt which are not roller-bearing-equipped, so little will be mentioned here of item (*d*). We will therefore confine our discussion to the application of items (*a*), (*b*), and (*c*). At the time of this writing, two main-line high-speed steam passenger locomotives have been in road service for some time with Timken lightweight revolving and reciprocating parts, including Timken-bearing-equipped crankpins and wrist pins. Service results have justified the extension of these applications to 53

[1] Vice-President, Timken Roller Bearing Company. Mem. A.S.M.E. Mr. Buckwalter entered the employ of the Pennsylvania Railroad at the Altoona Works in 1900, and after six years of shop experience transferred to the motive-power engineering department, continuing work on automotive-engineering matters until 1916. He developed electric baggage, mail, and express trucks generally used at railway terminals throughout the world. He was chief engineer of the Timken Roller Bearing Company from 1916 to 1922, and has been vice-president since 1923.

[2] Research Engineer, Timken Roller Bearing Company. Dr. Horger was graduated with a B.S. degree from the Carnegie Institute of Technology in 1923. Since October, 1923, he has been employed by the Timken Roller Bearing Co. During this time he spent three years in graduate study and research work at the University of Michigan under Prof. S. Timoshenko and received his M.S.E. degree in 1934 and Sc.D. degree in 1935. He is now in charge of applied mechanics research.

[3] General Manager, Timken Railway Division, Timken Roller Bearing Company. Mem. A.S.M.E. Colonel Sanders entered railroad work in 1908 as machinist's apprentice, Central of Georgia Railway, Cedartown, Georgia, and later attended Mercer University. He was employed as machinist in the Central of Georgia Railway shops, Macon, Georgia, and Atlantic Coast Line Railroad shops, Waycross, Ga., and then in the mechanical engineer's office, A.C.L. R.R., Wilmington, N. C. He served in France with the heavy artillery and Corps of Engineers and was graduated from the French Tractor Artillery School. Returning from France, he took a position with the equipment engineering department, New York Central Railroad. In May, 1923, he became associated with the Timken Roller Bearing Company as engineer of railway equipment in connection with development of Timken railway bearings. In 1931, Colonel Sanders was commended by the Assistant Secretary of War for his work on a general transportation plan for the War Department. Now Lieutenant-Colonel, U. S. Army Reserve Corps, assigned to the staff of the Assistant Secretary of War. He is the author of American articles on "Ball, Roller, and Sliding Bearings" and "Railway Rolling Stock" in the fourteenth edition of the Encyclopaedia Britannica.

Contributed by the Railroad Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

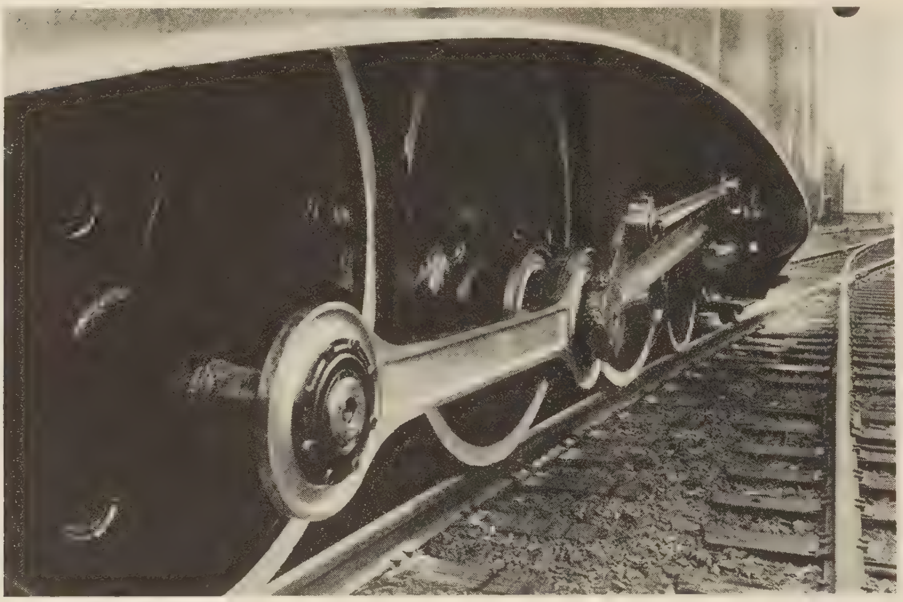


Fig. 1 The Timken Rod Application on New York Central High-Speed Streamlined Passenger Locomotive

(The crosshead and all crankpins of this locomotive were equipped with Timken bearings in 1935, and the side rods, main rods, crosshead, piston rods, and pistons are made to Timken design and of Timken steel. The use of Timken bearings and Timken high-dynamic steel in this design made possible a 52 per cent reduction of reciprocating weights, and a 22 per cent reduction of weight on the main pin. The engine-truck, and all driving and tender-truck axles have been equipped with Timken bearings since the locomotive was built in 1931. This locomotive is hauling the Twentieth Century Limited.)

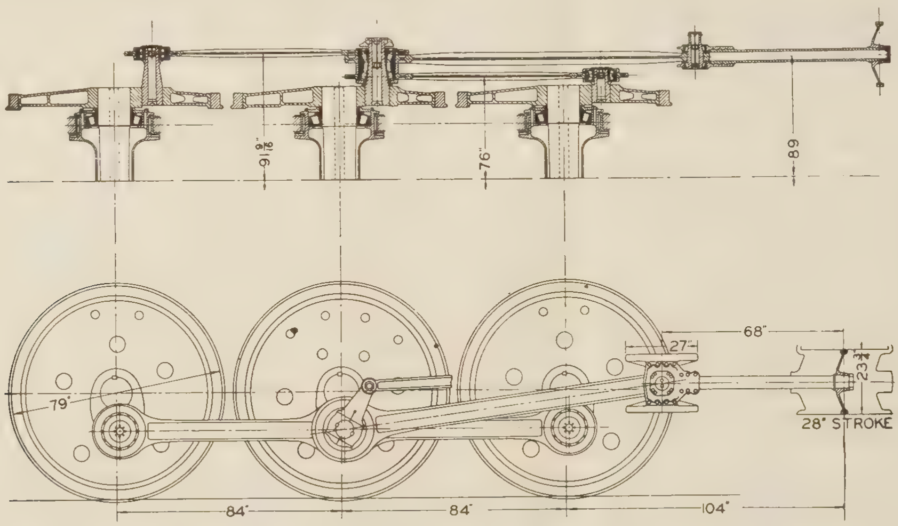

Fig. 2 Timken Lightweight Steel Driving and Running Gear for a 4–6–4 High-Speed Passenger Locomotive

additional locomotives now being built for various railroads, as indicated in Table 1 wherein locomotive specifications and road mileages are given. The influence and importance of such design changes on locomotive operation will now be discussed.

Lightweight Reciprocating and Rotating Parts

Importance of Lightweight Parts. The dynamic augment or hammer blow on the rail resulting from underbalance or overbalance of rotating parts increases with the square of the speed so that in going from 70 mph to 100 mph, a speed increase of 41 per cent, twice the dynamic augment is produced. Considering that there are certain limiting combined static and dynamic rail loads permissible on the track structure, the present motive power, with high static axle loading, does not permit doubling the dynamic augment. At diameter speed, the combined rail load is already about the permissible value.

In addition to the objectionable large dynamic augment developed at high speeds, other difficulties arise which are evidenced by increased nosing, swaying, and fore-and-aft oscillations of the locomotive. Vibrations of these types prevent smooth operation and lead to increased maintenance costs for both the track structure and the locomotive itself. The forces causing these vibrations are again proportional to the square of the speed.

Driving wheels on freight engines are frequently even too small to fully balance the rotating parts, so that the reciprocating weights remain entirely unbalanced. A large underbalance will result in excessive dynamic augment since every pound of un-

balanced rotating parts represents a rail blow of about 50 lb at diameter speed. In addition to this deleterious effect of large dynamic augment, this unbalance gives rise to horizontal forces which must be transmitted through the locomotive members and track structure. The maximum horizontal force on the locomotive frame, axle, and other parts is that due to the unbalanced rotating parts just mentioned plus that from the unbalanced reciprocating parts. This maximum force is about 70 lb for every pound of reciprocating and unbalanced rotating parts. If this force is allowed to become excessive at high speeds, additional strength in locomotive members will be required. Furthermore, these unbalanced weights result in forces producing nosing and fore-and-aft vibrations of the locomotive, although the long and heavy wheel base may tend to reduce the nosing.

The driving wheels on passenger locomotives are large enough to be properly balanced for all rotating weights and an ample percentage of the reciprocating parts. If a small percentage of the reciprocating parts are balanced, to favor a low dynamic augment, then the horizontal forces on the locomotive frame and running gear as well as vibrations from nosing and fore-and-aft movements would be excessive, although the use of the two-axle trailer trucks may improve the nosing condition. Thus, we come to the conclusion that counterbalancing offers no complete

solution to the problem since it is merely a compromise between balancing for the vertical and horizontal forces.

All this means that higher speeds will require either a reduction in the weight of the reciprocating and rotating parts, or improved and strengthened locomotive and track structure. Obviously, the former is the logical and economical procedure to follow, and such was the basis for the development of the Timken lightweight design. Weight reductions in reciprocating parts of 1072 lb per side and up to 52 per cent of the conventional designs have been made as shown in Table 1. The very favorable dynamic augment curves for the lightweight application in comparison with those for the heavy design it replaced are given in Fig. 6 for the axles of main driving wheels of locomotives given in Table 1. The curves show in general that it is possible by the reduction in weight to increase the diameter speed of steam locomotives by about 35 mph without change in dynamic augment. Curves similar to those of Fig. 6 could also be drawn to show the greatly decreased horizontal forces acting to cause vibrations and to stress the locomotive frame, axle, and other members. Means of obtaining this marked reduction in weights will now be discussed.

Description of Design. The general arrangement of the application of lightweight revolving and reciprocating parts is shown diagrammatically in Fig. 2. Its application on a modern high-speed passenger locomotive is shown in Fig. 1. As a general comment it should be noted that the shape of all the parts deviate considerably from conventional design and are determined by the proper distribution of metal to give maximum strength with minimum weight so far as this is consistent with good forging and machining practice. The general details of the application are apparent from the illustrations, but several of the salient features required to accomplish this purpose will be enumerated.

The eye ends of the rods are deep and narrow-width I-sections which efficiently give considerable rigidity and low bending stresses. This feature is to be contrasted with the usual wide and heavy rectangular section required to obtain the customary low plain-bearing pressures, which contribute to large bending stresses in the column section due to eccentric loading possible

over the wide ends, as indicated by a consideration of Fig. 3. The column stresses due to eccentric loading are reduced to a very low value because the narrow width of the rod ends and their simple knuckling action on the outer race of the bearing permit very little eccentricity. This knuckling action takes place on a $^3/_{16}$-in-thick rolled-strip phosphor-bronze bushing pressed into the rod eye and crowned on the surface floating over the outer bearing race. The column portion of the rods is an I-section, and, to carry the column and centrifugal stresses economically it is tapered from a center straight portion to a width of about six tenths as great at the ends. The usual knuckle-pin joints in side rods and the usual oil and grease holes through the rod eye, which introduce high local stresses and are the cause of many rod failures, have been eliminated. The rear side rod is located in a plane outside the main rod as a means of reducing the bending stresses and bearing load on the main crankpin.

The crankpins are made of thin-walled and tapered tubular sections. The crankpin bearings are of the usual Timken tapered design and are fitted directly to the crankpins. The crosshead pin also functions as the inner race of the bearing.

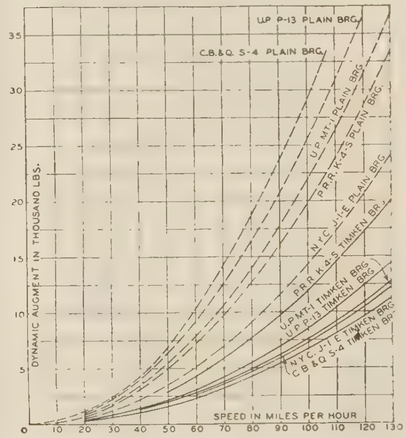

Fig. 6 Dynamic-Augment Curves for Main Drivers of Locomotives

(These curves show the reduced dynamic augment obtained by using Timken roller-bearing rotating and reciprocating parts rather than plain-bearing parts.)

[a] See reference (1) in Bibliography.

The piston rod is a thin-walled tube. The usual massive one-piece cast-steel crosshead is entirely redesigned, eliminating the taper-key connection and using a two-piece construction of thick plates die forged to proper shape. The conical piston is a forged and rolled shape of comparatively thin sections and its extremely low weight permits very successful operation with only two piston rings. The thin plate section of the piston permits deflections several times as great as the usual piston, and this is of value in reducing stresses when water is carried over from the boiler or from condensation in the cylinder. Comparison photographs of reciprocating assemblies for the conventional and Timken lightweight designs are shown in Fig. 4.

Before such service applications could be made on the driving and running gear it was necessary to give considerable study to (*a*) the selection of the proper materials and heat-treatment, (*b*) methods of manufacture, and (*c*) testing to facilitate stress analysis of the various members. This development, and particularly the testing, will be discussed in the first part of this paper, while the latter part will describe the fatigue testing of full-size driver axles as a means of reducing the stress concentration at wheel and bearing seats and increasing the fatigue strength of axles.

Selection of Material. The material selected for the rods, pistons, and principal members constituting the revolving and reciprocating parts is Timken high-dynamic steel of a Cr-Ni-Mo type, having the following nominal chemical analysis: 0.37 per cent C; 0.70 per cent Mn; 0.27 per cent Si; 0.75 per cent Cr; 1.60 per cent Ni; 0.25 per cent Mo. The approximate heat-treatment of all steel parts is a quench in caustic-soda solution or oil at 1440 F, after which a tempering treatment at 1200 F is given.

The average physical properties of this steel are shown in Table 2, and for comparison purposes similar properties are given for an aluminum alloy (1)[4] and for plain-carbon-steel forgings in accordance with A.A.R. specifications. The purpose of such a comparison is to show reasons for the selection of high-dynamic steel. In design parts of this nature it is desired to have a material possessing high yield strength, high endurance limit, good ductility as measured by elongation and reduction in area, favorable impact strength, and to obtain these properties with minimum weight as expressed by the strength-weight factors. Also good forging, heat-treating, and machining characteristics are required.

Commenting on Table 2, we find the favorable high values of strength-weight factors for Cr-Ni-Mo steel relative to yield strength and endurance limit. The value of the tensile strength is not of much importance because failure in such design parts is based on static stresses which cause yielding[5] or variable stresses which develop fatigue failure.[6] The only exception to the use of the Cr-Ni-Mo steel is in the crosshead shoe, which is an aluminum forging.

Forging Process. The driving rods, piston, and crosshead are all die forged; the piston rod is made from cold-drawn steel tubing, and the crankpins are hammer forgings. In order to obtain the beneficial effects of grain flow, the development of die shape and forging technique was required. As an example of the uniform and maximum strength characteristics obtained by favorable grain flow, Fig. 5 indicates the tensile-test results of specimens selected from various positions in the eye end of a side rod, which portion presents the greatest difficulties in producing proper grain flow. A number of longitudinal etched sections of the eye were made to determine the proper grain flow so that in the subsequent machining operations the cutting would be parallel and not transverse to these flow lines. Only $1/8$ in. to $3/16$ in. of stock is left on each surface for machining, except at the rod bore where $1/4$ in. is allowed. A typical example of the die-forging process followed in making the rods will be given.

FIG. 7 TAPERED-COLUMN TEST RESULTS

The eye end and a little over half of the column section of the rod is die forged in three operations consisting of forming, blocking, and finishing operations. The opposite end of the rod is then die forged in a similar manner. A center die is then used to straighten the column section with the ends and to control the length.

The forming begins by hot upsetting the end of a 7-in. round billet into a sphere after which this sphere is flattened into a pancake-shape in the plane of the rod. This blank is then placed in a 1500-ton hydraulic press for the blocking operation where it is pressed into the die shape of the column and eye sections. The final forging is then done in finishing dies on an 18,000-lb drop hammer. The proper temperature of the forging must be maintained during each of these operations by reheating. A steam jet is used to remove all scale after each hammer blow.

The trimming of the flash is done in three operations. The thin plate left in the bore of the eye is removed after the blocking, the outer flash is removed after the completion of one half

[4] Numbers in parentheses refer to the Bibliography at the end of the paper.

[5] The reason for the favorable influence of high yield strength is discussed later in the paper under column design of rods.

[6] As an example, variable stresses occur in the eye-end sections of the rods; this is discussed later in the paper

the finish forging, and final trim is made after completion of the forging. The total weight of the trim is very small. A complete description of this forging process is given in *Iron Age* (2).

Design of Column Sections of Rods

The design of the column sections of the main and side rods is based on compression tests of full-size tapered columns. The columns tested were machined from standard structural-steel I-beam sections to dimensions comparable with those of full-size main and side rods used in service. The object of these tests was to determine the load required to bring failure due either to local yielding or to buckling. Only sufficient tests were made to satisfy the validity of formulas (4) for the rational design of tapered columns.

Column Tests. The general shape and characteristics of the columns tested are shown in Fig. 7. For a column tapered in the manner shown, the least moment of inertia of any cross section in the tapered portion at either end of the column is very nearly proportional to the cube of the ratio of the width of flange at that section to the width of flange at the end of the column. The buckling load for a pin-ended column of this kind is expressed by the equation

$$P_c = m\frac{EI}{L_0^2} = m\frac{EAR^2}{L_0^2} \quad\text{[1]}$$

where E = Young's modulus (30×10^6); I = least moment of inertia of the uniform section at the center of the column; A = cross-sectional area of this section; R = least radius of gyration of the same section; L_0 = over-all length of the column; m = coefficient (Dinnik's factor) dependent on the ratios l/L_0 and i/I; l = length of uniform part of the column; and i = least moment of inertia of the section at either end of the column. Values of the coefficient m were taken from a table for pin-ended tapered columns given in Dinnik's work (4) and the buckling load was calculated for each column tested as shown in Fig. 7.

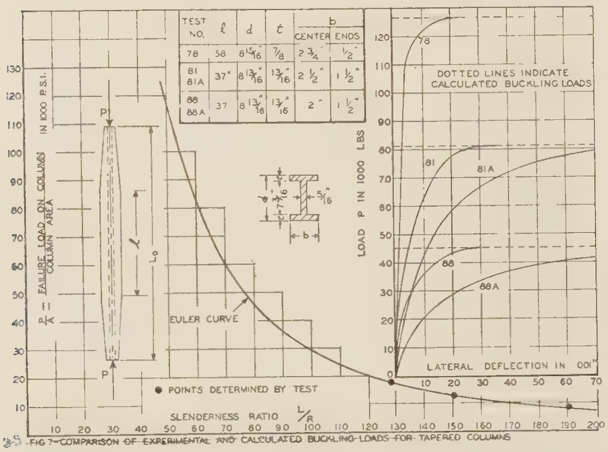

Fig. 8 Comparison of Experimental and Calculated Buckling Loads for Tapered Columns

For a uniform column, Equation [1] for the buckling load reduces to Euler's formula

$$P_c = \pi^2\frac{EI}{L^2}$$

or

$$\frac{P_c}{A} = \pi^2\frac{E}{(L/R)^2} \quad\text{[2]}$$

where L = length of the uniform column; A = cross-sectional area; and R = radius of gyration of the cross section. From Equation [2] Euler's curve has been plotted in Fig. 8. A modified Euler curve could be drawn for each value of m encountered in the column tests, and individual test results could be compared with the corresponding curves. Instead of doing this, a simpler procedure was adopted for the comparison of test values with the values predicted by theory. For each column tested, the length L was calculated for an equivalent uniform column, having a cross section the same as that of the center part of the

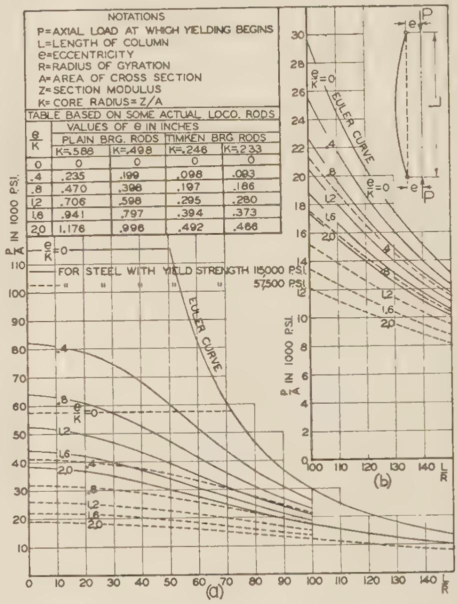

Fig. 9 Stress in Columns of Various Slenderness Ratios

(These curves show that the allowable P/A stress, above which yielding will occur at the center of an eccentrically loaded column, is greater for columns made of steel having a yield strength of 115,000 lb per sq in., than it is for columns made of steel having a yield strength of 57,500 lb per sq in.)

tapered column, which would buckle at the same load. Using this value of L, the test value of P_c/A for each column tested could be plotted against L/R for that column and the point so obtained should fall on Euler's curve.

The table in Fig. 7 gives the dimensions and other data for three of the seventeen different designs of columns tested. The test results given in this table represent the results of five tests, one test on the first design and two each on the other two designs. In each case, the buckling loads for the two tests on the same design were identical. The load-deflection curves for these five tests are given in Fig. 8. The slope of each curve showing the lateral deflection of the column at its center is due to slight and unavoidable imperfections in material, initial curvature of the column, and accidental eccentricity of the load applied in the test. For an ideal column, the curve would be truly vertical for loads up to the failure load. The actual curves are asymptotic to the horizontal dotted lines which show the theoretical calculated value of the buckling load for each column. The test value of P_c/A for each of the three designs of Fig. 7 is plotted against L/R in Fig. 8 as three points, which fall on the Euler curve. The close agreement of the experimental points with Euler's curve shows that the analytical work of Dinnik can be applied to find an equivalent value of L for a tapered column. This equivalent length will be greater than the actual length L_0 of the column, and the column may then be designed for safety from buckling or failure at the middle of the column as

though it were a uniform column of length L. The experimental results presented in this paper in support of this idea were obtained from tests on tapered columns having very little eccentricity. However, additional tests on tapered columns were carried out in which the loads were applied with a deliberate eccentricity at both ends of the column. These tests showed that the correspondence between the measured deflections at the center of an eccentrically loaded tapered column and the calculated deflections at the center of the equivalent uniform column, the

FIG. 10 CURVES SHOWING THAT THE ALLOWABLE P/A STRESS, ABOVE WHICH YIELDING WILL OCCUR AT THE ENDS OF AN ECCENTRICALLY LOADED TAPERED COLUMN, IS GREATER FOR COLUMNS MADE OF STEEL HAVING A YIELD STRENGTH OF 115,000 LB PER SQ IN., THAN IT IS FOR COLUMNS MADE OF STEEL HAVING A YIELD STRENGTH OF 57,500 LB PER SQ IN.

length of which was determined as previously explained, was sufficiently close to warrant using the same equivalent length L for the design of a tapered column regardless of the amount of eccentricity assumed to exist in the application of loads.

Failure of Uniform Columns. With this in mind, we can proceed with a discussion of the failure of uniform columns. Euler's curve shown in Fig. 8 gives the buckling load for pin-ended columns with no eccentric loading. If we consider that a column has failed as soon as the yield-point strength has been exceeded, then the full-line curve designated as $e/k = 0$ (see Fig. 9 for notations and table of values of eccentricity e for actual locomotive rods) in Fig. 9 gives the failure loads for columns with no eccentricity if the steel in the columns is of the Timken high-dynamic type, having a yield-point strength of 115,000 lb per sq in. The horizontal portion of this curve is below the value of L/R used for locomotive rods and is not of much interest to the designer. For a detailed discussion of short columns see the paper by Westergaard and Osgood (5). In a driving-gear system, moreover, the load is sometimes eccentrically applied on the rod and develops stresses above the yield point as a result of the combination of bending stress with direct stress. The remaining full-line curves of Fig. 9 are also for a yield-point strength of 115,000 lb per sq in., and show the loads at which yielding at the center of a uniform column will begin for several assumed values of the ratio e/k. The curves shown in Fig. 9 were calculated using the equation

$$\frac{P}{A} = \frac{\text{Yield-point strength}}{1 + \frac{e}{k} \sec \frac{1}{2} \frac{L}{R} \sqrt{\left(\frac{P}{EA}\right)}} \qquad [3]$$

the notations for which are given in Fig. 9. This equation is found in a paper by Young (6). The dashed-line curves of Fig. 9 give the same information as the full-line curves, only for a steel having a yield-point strength of 57,500 lb per sq in. Fig. 9*a* shows both groups of curves for values of L/R up to 150. In Fig. 9*b* is given that portion of the curves to an enlarged vertical scale for L/R values of 100 to 150 which are commonly used in locomotive-rod design.

The curves of Fig. 9 furnish a basis for the rational design of columns by assuming some eccentricity and utilizing steels with higher yield strength. The factor of safety for any column will be the ratio of the load at which the column will yield to the maximum load which the column must carry. It is apparent from Fig. 9*b* that with equal eccentric loading (say e/k = 2.0) the higher yield strength steel will give a column strength 24 to 43 per cent greater than the lower yield strength steel for L/R ratios of 150 and 100, respectively. As mentioned before, the narrow width of the ends of the Timken rods and the well-maintained alignment of the driving axles and driving-rod system through the use of Timken roller bearings permits small eccentric loading compared to plain-bearing rods. Assuming that e/k may be reduced from 2.0 to 1.0, then Timken rods made from steel with a high yield strength will have a strength of from 40 (L/R = 150) to 76 per cent (L/R = 100) greater than plain-bearing rods of the same weight made from steel with low yield strength. Or by maintaining the same column strength in designs using both steels, the Timken rods will show a saving in weight.

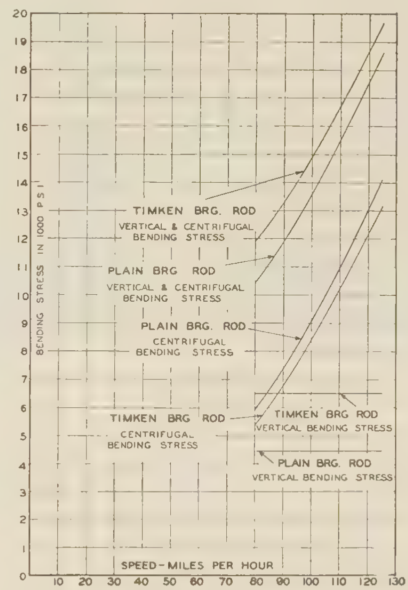

FIG. 11 VERTICAL BENDING AND CENTRIFUGAL STRESS IN MAIN RODS

Yielding at the Ends of Tapered Columns. While the curves of Fig. 9 illustrate saving in weight effected by using steel of high yield strength for uniform columns, we will also show by Fig. 10 that the use of the same steel gives additional weight saving by increasing the amount of taper which may be permitted at the ends of the columns or rods. When the ends of a column are tapered, failure may develop due to local yielding at the ends of the column before buckling or yielding occurs in the middle. The stress at the end of a column is independent of deflections, so that the maximum combined stress at the end of a tapered column is simply

$$\frac{P}{A} + \frac{Pe}{Z} \quad [4]$$

where the notations are those in Fig. 10. To find the value of P/A at which yielding will begin at the end of a column it is only necessary to equate this stress to the yield-point strength of the material. Fig. 10 gives curves showing the values of P/A at which yielding will begin at the ends of a tapered column, one curve for the Timken high dynamic steel having a yield point strength of 115,000 lb per sq in., and the other for a steel having a yield strength of 57,500 lb per sq in. The curves show that the value of P/A to cause yielding for a given column end section is directly proportional to the yield-point strength of the material

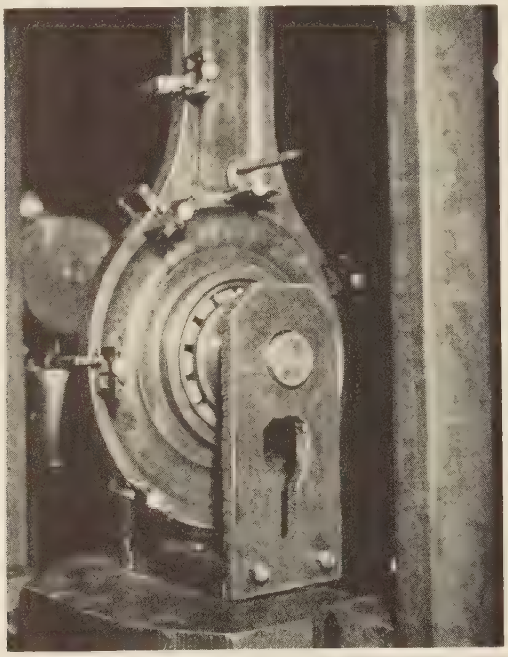

Fig. 12 Side Rod in Test Setup Showing Arrangement of Strain Gages Used to Determine Stress Distribution in Various Eye Sections

used. In using the curves in Fig. 10 it should also be considered that here again much less eccentric loading may be expected on the narrow Timken rods than on the wide plain-bearing rods for the reasons previously mentioned.

On the basis of the test results and theoretical considerations presented previously in this paper, we conclude that tapered-column sections used in locomotive main and side rods may be designed for safety against sidewise bending and direct stress by the use of curves derived from rational formulas. It should be mentioned here that empirical formulas similar to those used by A.A.R. and locomotive builders do not permit the proper evaluation of the advantages to be obtained by using the higher-yield-strength steel and tapered-column design.

Fatigue Failure of Rods. Up to this point, only static failure of the columns has been considered, but the possibility of fatigue failure must also be investigated. Fatigue failures seldom occur in the uniform-column portion of the rod, but usually develop at the junction of the column with the eye (fatigue failures in the eye will be discussed later). In this region there is usually an abrupt change in section, and the bending and direct stresses are higher than the nominally calculated values due to stress concentration. The Timken-rod design gives comparatively uniform sections at the junction of the eye and column which results in less stress concentration and greater uniformity of strength of material than in the plain-bearing rods. The danger of fatigue failure in the Timken rods is further reduced by the high fatigue strength of the high dynamic steel.

Vertical Bending and Centrifugal Stresses. At low speeds, only sidewise bending and direct stress need be considered. At high speeds, however, stresses due to vertical bending caused by the column load and inertia forces on the rods must be considered. Fig. 11 shows a comparison of these stresses for the Timken main rod on a locomotive and the plain-bearing rod which it replaced. The centrifugal stresses were calculated from the usual formula as recommended by the American Locomotive Company and the A.A.R., and derived in Merriman's "Mechanics of Materials." The formula recommended by the American Locomotive Company for the calculation of vertical bending

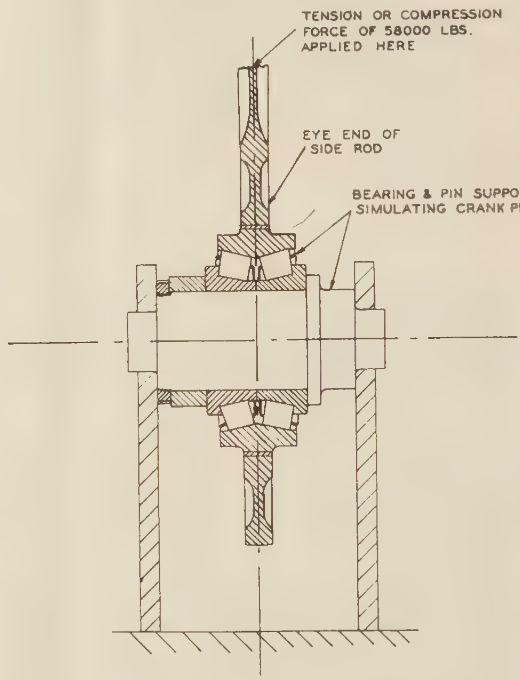

Fig. 13 Arrangement of Test Setup of Side Rod to Determine Stress in Eye Section by Means of Strain Gages

(Locations of strain gages at various positions on the eye are shown in Fig. 14.)

stress S in a rod, is an empirical formula which can be written in the form

$$S = \frac{P/2A}{1 - (P/2\,P_e)} \quad [5]$$

where P is the maximum piston thrust, and P_e is Euler's load for buckling in the vertical plane as given in Equation [2], considering the rod as a round-ended column. The curves for vertical bending stress given in Fig. 11 were calculated from this formula. Fig. 11 shows also the combined stress, vertical bending plus centrifugal, for the Timken rod and the plain-bearing rod. It will be seen that the combined stress is slightly higher for the Timken rod because of its reduced section. The higher stress in the Timken rod is more than offset by the higher physical properties of the steel used as compared with the properties of the steel used for plain-bearing rods.

The practice of combining vertical bending with centrifugal

stress, as in Fig. 11 is recommended by the American Locomotive Company. The standard practice of the A.A.R. is to combine direct stress due to a fraction of the full piston thrust with centrifugal stress. The latter method would give slightly lower stresses than those shown by the curves in Fig. 11.

Design of Eye Ends of Driving Rods

Examination of Figs. 1 and 3 showing the eye-end sections of the Timken main and side rods reveals the wide departure from usual design practice, in that light I-sections are used instead of heavy rectangular sections. On account of this great difference in shape of sections, it was not advisable to employ the established empirical formulas of the A.A.R. and locomotive builders in arriving at the proper design of eye for the Timken rods.

A satisfactory analytical solution for the stresses in the eye ends of the main and side rods does not exist. This is due to the difficulty of determining the load distribution over the bore of the rod eye which depends upon the clearance between the eye and the bearing race (7). This clearance is a minimum for new parts and, since increased clearance results in higher stresses in the eye sections of the rod, the stresses in these sections become greater as the clearance increases under operating conditions. The purpose of these static tests on full-size eye sections, therefore, was (*a*) to investigate the stress distribution in various designs of eye sections, and (*b*) to determine the increased magnitude of these stresses due to increasing the clearance from minimum to maximum values anticipated in service. These tests were made on side rods and the knowledge obtained was applied in an analytical solution for the stresses in the main rods which are of similar design. In addition to the stresses measured in these static tests, stresses due to impact are present in the eye sections under operating conditions and this must be considered when a factor of safety is selected.

Tests of Side-Rod Eyes. The method of loading the eyes of the side rod in the testing machine to determine the stress distribution by means of last-word strain gages of 1-in. gage length located at various I-sections is shown in Figs. 12 and 13. The complete stress distribution was determined in the eye section for ten different rod conditions which included the investigation of five different eye designs having various clearances between the eye and the outer race of the Timken bearing. A total of 1300 strain-gage readings were made, most of which were obtained from tensile tests on the rods and the remainder from compression tests. As shown in Fig. 13, a load of 58,000 lb (one half piston thrust) was applied on the side-rod eye in all these tests which is in accordance with A.A.R. design specifications for the six-coupled passenger locomotive on which this rod application was made. The results of two of the tension tests on each of the two designs of eyes in Fig. 14 are shown graphically in that figure. Strain gages could not be mounted closer than $^{1}/_{16}$ in. from the boundary of the rod so that stresses at this position are given in the table of Fig. 14 rather than stresses extrapolated to the boundary.

Summary of Stresses Due to Both 0.004-In. Press Fit of Crosshead Pin and 117,400-Lb Pull on the Main Rod

	Section U	Section N
(*A*) Measures stress, lb per sq in.	21,800	20,900
(*B*) Stress $P/2A$, lb per sq in.	13,000	8100
(*C*) $(A)/(B)$	1.68	2.58

Referring to Fig. 14, it is apparent that the critical stresses measured in test occur at sections N and U with the latter showing the maximum stresses. Actually the maximum stresses exist a short distance from section U, depending upon the clearance in the eye, but the difference from the values shown would be small. The table in Fig. 14 shows slightly lower stresses for design 2 than for design 1, particularly with increased pin clearance. This may be explained by the increase in hub thickness from $^{7}/_{8}$ in. in design 1 to $^{15}/_{16}$ in. in design 2 and by the longer radius of $14^{3}/_{4}$ in. used in design 2 compared to 12 in. in design 1. The thinner rim in design 2 would tend to increase the stress over design 1. The effect of $^{5}/_{64}$ in. pin clearance instead of $^{1}/_{64}$ in. clearance is to increase the stresses by 13 to 20 per cent at section U, but is of greater influence at section N where the stresses with $^{5}/_{64}$ in. clearance are 1.7 to 2.2 times as great as the stresses with

$^1/_{64}$ in. clearance. The measured stresses given in the table in Fig. 14 for section U are 3.1 to 3.9 times the nominally calculated direct stresses, $P/2A$, and are 1.5 to 3.2 times as great as $P/2A$ at section N, which indicates the presence of considerable bending at these sections.

As a result of the test data given and additional tests not shown, the final design of rod introduced in service applications incorporated features of both designs 1 and 2, which would give stresses more favorable than those shown in Fig. 14.

Several investigators have made tests (1), and analytical (8, 9, 10) and photoelastic (11, 12) analyses of the stresses in eye bars. The difficulties in applying their solutions and results were principally due to the facts that their investigations were made on eye bars having rectangular sections, and that the determination of distribution of pressure around the bore as affected by pin clearance necessitates lengthy solutions. Given more time it is believed that a satisfactory correlation could be made between the stresses obtained by test and the analytical values.

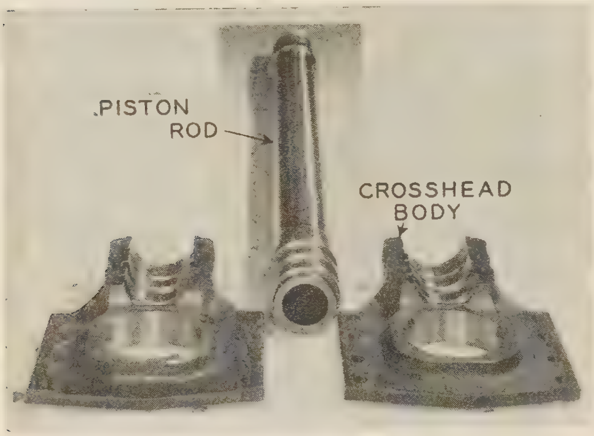

Fig. 16 Two Halves of Die-Forged Crosshead Body Bolted Together Over System of Annular Grooves in Piston Rod to Form Crosshead Connection

Tests of Front End of Main Rod. Similar strain-gage tests were also made on the front end of the main rod to determine the stresses in the rod due to both the cylinder pressure and the press fit of the crosshead pin in the rod. The results of these tests are shown in Fig. 15. The stresses in the rod resulting from the 0.004-in. press fit of the crosshead pin were measured first, and are shown by the broken-line curves in the figure. Then 117,400-lb pull was applied on the rod, increasing the stresses to the values shown by the full-line curves, which represent the combined stress due to both the press fit and the pull. The pull force on the rod increased the stress by 17 per cent at section N and 36 per cent at section U over that due to the press fit. The variation in stress in going from tension to compressive forces in the rod will therefore be small in actual operation and this is a favorable condition for maximum fatigue strength. The measured stress at section U in the bore is 1.7 times the nominally calculated direct stresses, $P/2A$, and 2.6 times at section N. The measured stresses due to the press fit give reasonable agreement with calculated values based on Lamé's formula in view of the assumptions necessary in making such a comparison.

It is necessary to maintain sufficient press fit of the pin in the rod if it is not to work loose in service. Besides the tests just mentioned additional tests were made on the front end of the main rod. The results of these tests indicate that it is desirable to make the rod eye from 0.002 in. to 0.004 in. tight on the crosshead pin.

Crosshead Test

A comparison illustration of the assemblies constituting the reciprocating parts is shown in Fig. 4 for the lightweight and conventional designs. The usual design of taper key fit of the piston rod in the cast-steel crosshead contributes considerable

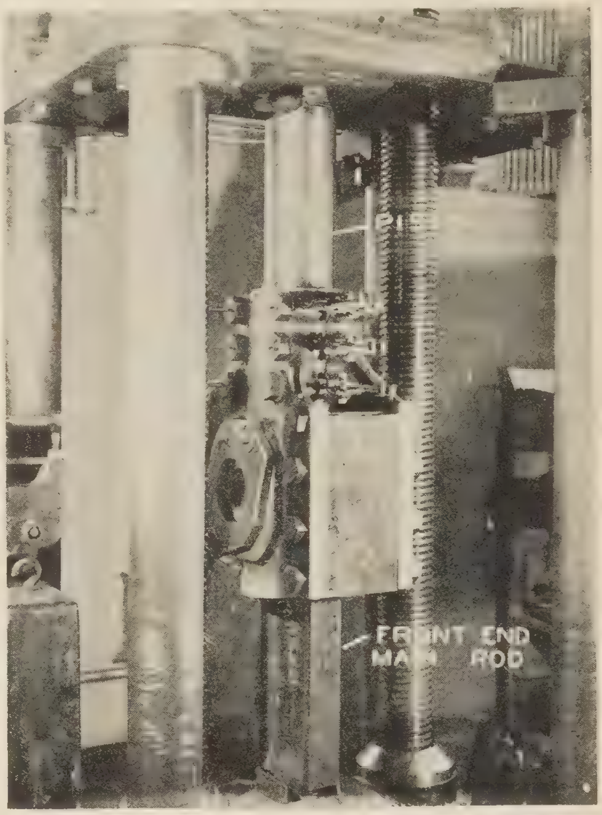

Fig. 17 Crosshead Test Setup Used to Determine Stress Distribution in Annular-Groove Connection Between Piston Rod and Crosshead

(Illustration shows the method of determining piston-rod stresses by means of Huggenberger strain gages mounted on gage pins fixed to piston rods and extending through clearance holes in the crosshead.)

weight to the reciprocating parts and is not used in the Timken design. In this lightweight design a piston rod having a $^3/_4$-in. wall section is keyed by three integral annular grooves on

the end of the piston rod to a crosshead consisting of two thick die-forged side plates as shown in Fig. 16. The object of the following described tests was to develop the proper design and system of annular grooves to provide a rigid connection and proper distribution of load over the several annular grooves. This problem is somewhat similar to that in bolts where there is a concentration of stress in the first few threads (13, 14), and in the

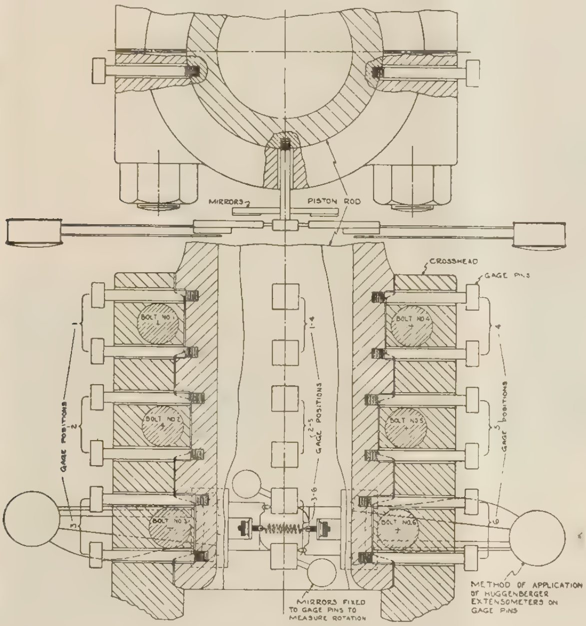

Fig. 19 Method of Mounting Huggenberger Strain Gages and Mirrors on Gage Pins Fixed to Piston Rod and Extending Through Clearance Holes in Crosshead. Used for Determining Stresses in Annular Grooves in Piston-Rod Connection at Crosshead

crosshead design the groove shape and spacing as well as shape of crosshead body was modified to give a more even stress distribution.

A general view of the crosshead assembly located in the tensile-test machine is shown in Fig. 17 and a close-up in Fig. 18. Strain measurements were obtained on the piston rod at the base of the annular grooves by means of gage pins fixed to the rod and extending through clearance holes in the crosshead as shown in Fig. 19. Huggenberger gages were then applied to the extended gage pins to measure the change in distance between pins, and telescopes were sighted on mirrors attached to the pins to determine their change in angularity. It was necessary to measure change in angularity of pins since the Huggenberger strain gages could not be mounted directly on the piston rod. By correcting the Huggenberger reading for change in angularity of the pins an equivalent strain at the base of the annular grooves was obtained. Preliminary strain measurements of this kind were made to determine the longitudinal stresses at the surface of the piston rod due to tightening the six bolts fixing the side plates to the rod. A tensile force of 120,000 lb was then applied to the piston rod and the measurements were repeated.

Stresses in the piston rod at the base of the annular grooves were determined for two different designs of annular-groove systems and these designs as well as test results for both are shown in Fig. 20. The bolts were drawn equally tight for the test on each design. The stresses in the bolts were determined by measuring the change in length of each bolt with 0.0001-in. dial gages. Consideration of the factors of magnitude and uniformity of stresses in Fig. 20 leads to the selection of the second design, which is the one that was adopted for actual service applications with slight modifications. The stresses given are average stresses at the surface of the piston rod based on a gage length of $1^3/_8$ in. and the local stresses adjoining the fillets at the base of the annular grooves would be higher than the stresses shown. These fillet stresses, however, are calculated to be well within the endurance limit of the steel.

For locomotive applications, the system of annular rings is

machined to close tolerances, using gages, and then the piston rod is lapped-in to the crosshead body. By this procedure the desired fit and magnitude and distribution of stresses in the crosshead assembly are obtained.

Axle Design

This part of the paper discusses (*a*) the fatigue strength of axle assemblies, particularly the weakening effect due to the press fit of the wheel on the axle, and means of correcting this weakness, and (*b*) the impact forces on axles at high speeds and also how the axle design may be modified to reduce such dynamic forces.

Fatigue Testing of Full-Size Axles. In order to investigate the fatigue strength of full-size axle assemblies up through 14 in. diameter, the Timken locomotive-axle testing machine[7] shown in Fig. 21 was placed in operation in the Timken research laboratory late in 1936. At the present time full-size outboard driver axles having a wheel-seat diameter of $11^1/_2$ in. are being tested in

[7] Built by Riehle Testing Machine Division of American Machine & Metals, Inc., under the direction of A. Sonntag, chief engineer.

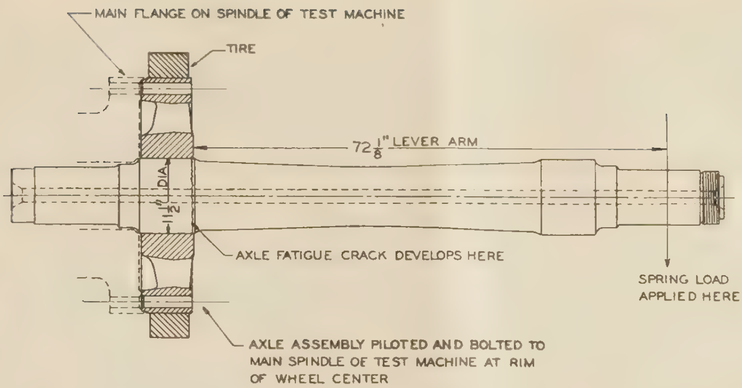

Fig. 23 Details of Axles Tested in Fatigue Machine

cooperation with the Pennsylvania Railroad. Fig. 22 shows a close-up view. Fig. 23 shows the details of this size axle now being tested. The operation and method of testing is self-explanatory from a study of Figs. 21, 22, and 23, but it may be added that two axles may be tested simultaneously, one at each end of the machine, loaded as cantilevers and at different bending stresses. The load is applied on the end of the axle by means of calibrated springs of long travel characteristics to give accuracy of load and reduce to negligible values the effects of any pulsating load due to eccentricities in the running of the axle.

Axle-fatigue failure develops within the wheel fit a short distance from the inside wheel hub face. This location is shown diagrammatically in Fig. 23. Fig. 24 shows a typical axle failure produced on the testing machine shown in Fig. 21. The general nature and location of this axle failure in Fig. 24, is comparable to that produced under service conditions.

At the time this paper was written, sufficient data had not been developed on the fatigue strength of full-size axles to justify even preliminary conclusions. When this paper is presented at the Detroit Meeting in May, additional data will be available. In the meantime, however, we may obtain some conclusion as to the low fatigue strength from the fact that the axle failure shown in Fig. 24 developed at a bending stress of 19,000 lb per sq in. after 5,730,000 rev. The material is a low-carbon 3.1 per cent nickel steel, normalized and tempered.

Scale-Model Tests on 2-In. Axles. As a forerunner to these full-size axle tests, several years experience are available (15, 16, 17) on the fatigue testing of 2-in. diameter scale-model axle assemblies. Approximately two-hundred 2-in. axles have been tested. Also other investigators (18, 19, 20) have studied this problem on $^5/_8$ in. and $1^5/_8$-in. diameter test axles. These tests on 2-in. axles are being continued parallel to the full-size tests so that a correlation may be made to determine the influence of size effect.

Considerable information is now available (15, 16) on these scale-model tests to conclusively show that the fatigue strength of 0.45 per cent plain carbon steel, normalized and tempered, is decreased from 34,000 lb per sq in. without a press-fitted wheel, to about 14,000 lb per sq in. with a press-fitted wheel or only 41 per cent of the strength available and that this greatly reduced strength is a result of high stress concentration introduced by the wheel fit. Several

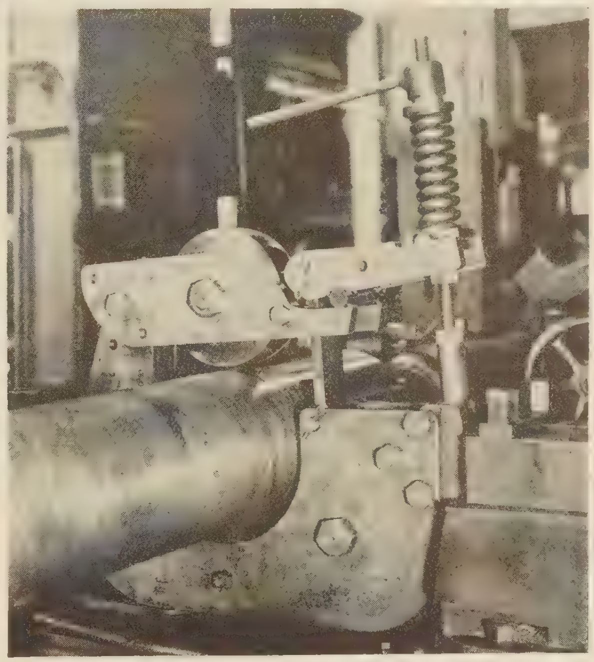

Fig. 25 Method of Surface Rolling 12-In. Diameter Driver Axles to Obtain Increased Fatigue Strength

(Spring pressure is applied through a calibrated spring and lever arrangement to three rollers spaced 120 deg apart which are mounted in a cradle supported on the traveling lathe carriage. Only the top roller is visible.)

means of improving this weakness have been developed and the most effective method is burnishing or cold rolling of the axle (17) in the region of the press-fitted members, as shown in Fig. 25. This rolling operation more than doubles the fatigue strength of the axle. Other methods such as relief grooves in the wheel hub face, raised axle seats at the wheel fit, and various steels and heat-treatments do not appear to give more than about 10 to 25 per cent increased strength for any one such method. Our schedule of tests includes the investigation of all these effects and others on both 2-in. and full-size axles. The stress concentration and weakening effect of axle fillets will also be investigated at a later date.

Impact Stresses in Axles. The usual empirical methods of determining axle design are based on using either (*a*) the static load plus allowance for vertical oscillations and low allowable design stresses, or (*b*) an axle loading similar to that in (*a*) in addi-

tion to large flange thrust, similar to the Reuleaux method which permits the use of higher allowable design stresses. Axles designed in this manner consider stresses determined by the axle diameter only as it affects the section modulus and do not express the dynamic stresses dependent upon the rigidity and unsprung weight of the axle assembly. Under conditions prevailing in present high-speed service, it becomes necessary to consider these additional factors in order to determine combined stresses which lead to axle failure.

The problem of weight requires no further explanation than to state that all unsprung parts should be made as light as possible. This discussion will then deal principally with the rigidity of the axle which may be simply defined as the resistance of the axle to deflection under a certain force. Any impact between the wheel and rail develops a certain energy, most of which must be absorbed in the unsprung-weight system. If we imagine the axle between the wheels as being a very elastic member, then much of this energy would be expended in deflecting the axle with resultant small impact forces in the axle compared to the case where a very rigid member connects the wheels.

In practice, the portion of the axle between the wheels is comparatively rigid and this is especially true with inboard axles where this portion is about the same diameter as wheel and bearing seats. This portion of the axle could be safely tapered to a much smaller diameter, which would result in lower axle impact stresses due to increasing the ability of the axle to deflect. This smaller diameter is further justified when one considers that (*a*) the bending moment gradually decreases between the bearing and wheel seats, and (*b*) a stress-concentration factor of at least two exists at wheel and roller-bearing seats due to the fitted members on the axle. This would mean that the center of the axle could have a diameter with a section modulus as small as one half of that at the wheel and bearing seats. As a specific example, an axle with 12-in. diameter wheel and bearing seats would be tapered to $9^1/_2$ in. diameter at the center, provided wheel gage may be maintained with axle under load.

What has been said previously, relative to inboard axles, also applies to outboard axles. We find, however, that outboard axles are already tapered to a smaller diameter at the center in the portion between the wheels. Very little test information is available to indicate just what axle proportions are best. A number of inboard- and outboard-type axles have failed in service at the wheel fit and the usual remedy has been to make the replacement axles not only larger at the wheel seat but also at the portion between the wheels. The usual empirical formulas applied to such designs would indicate lower calculated stresses at the wheel seat but they do not show the increased stresses due to the dynamical effect of greater weight and especially increased rigidity. When such axle failures develop it would appear to be better design to increase only the wheel-seat diameter and not to alter the portion between the wheels or in some cases even to make the center portion smaller in diameter.

It has already been reported on electric-locomotive lead-truck axles (3) that vertical accelerations on the unsprung journal box measured 7 to 13 times gravity, whereas on the main frame the acceleration was gravity. More data of this type would assist in making an intelligent analysis of this problem. From what has been said about the dynamical effects it is recommended that consideration be given to the study of modifying the present proportions of the ratios of axle, wheel- and bearing-seat diameters to the diameter of axle at the portion between the wheels.

Acknowledgment

The authors are indebted for the interest and cooperation of various railroads in connection with this work, which was conducted by the engineering staff of the railway division of The Timken Roller Bearing Company. The full-size axle tests are being developed in cooperation with the locomotive-design committee of the Pennsylvania Railroad. Beneficial discussions in connection with the paper were also had with Dr. S. Timoshenko, of Stanford University.

Oil-Film Thickness at Transition From Semifluid to Viscous Lubrication

By G. B. KARELITZ[1] and J. N. KENYON,[2] NEW YORK, N. Y.

This paper describes tests in which flat-faced pieces of several bearing metals were mounted to ride on a small journal which was lubricated by means of an oil bath. The initial lines of contact gradually developed into grooves until viscous oil films formed between the rubbing surfaces and arrested further wear. The minimum thickness of these wedge-shaped oil films were computed from observations made with tin-base, lead-base, bearing-bronze, and leaded-copper bearing metals, each being tested under loads of 20, 40, and 60 lb per sq in., respectively. It is shown that the film thickness is substantially independent of the load for any one individual material, ranging from 0.00003 in. to 0.00006 in. Photomicrographs of the surface structures of the bronze and tin-base babbitt are shown, which permit measurement of the height of excrescences. These measurements compare favorably with the computed values of minimum oil-film thickness. The observations are correlated with those given by McKee (6),[3] obtained on the running in of small bearings. The effect of different oils on the running in of babbitt is also indicated.

It IS considered in the theory of lubrication that a transition from viscous to semifluid friction occurs in a bearing when the minimum oil-film thickness is equal to the combined height of protrusions on the rubbing surfaces. Under these conditions the protrusions come into contact and begin to increase the coefficient of friction in the bearing. The experiments described in this paper were made for the purpose of ascertaining the thickness of the oil film when this transition takes place. It was reasonable to assume that the film thickness would vary for different materials, but would be the same for any given pair of metals under different loadings, and with the same lubricant.

Experimental Setup

The apparatus for the tests was suggested by the work of Connelly (1) and is shown in Figs. 1 and 2. It consists of a test shaft mounted on two ball bearings and connected with a small d-c electric motor. The shaft has a cantilever extension of $^5/_8$ in. diameter rotating in an oil bath which is maintained approximately at a level with the shaft center. The oil reservoir, shown in Fig. 2 replenishes the oil lost by leakage through the ball bearing adjacent to the bath.

A $1 \times 1 \times {}^1/_2$-in. bearing-metal test block is mounted on the loading lever and is held in place with a wing nut. The block rests on the test shaft as shown in Fig. 2. The loading lever is fulcrumed on a ball-bearing hinge and loaded at the other end by weights carried on a rather flexible spring. The lever ratio is 5:1. The dead weight of this loading arrangement is adjusted to give a 5-lb load on the test journal.

When the shaft rotates, oil is carried up and lubricates copiously the rubbing surfaces of the block and journal. A 0.0001-in. dial gage is mounted on a rigid arm so that its plunger may be brought in contact with the loading lever. This dial indicates the gradual sinking of the lever as the test block wears away by friction; it also gives an indication of the vibrational effect due to inaccuracy of the test shaft.

A thermometer is used to measure the temperature of the oil bath. An ammeter in the motor line shows the variation in the frictional torque on the shaft. Due to high losses in the small driving motor, the ammeter readings have only a relative value.

Test Procedure and Estimate of Film Thickness

The test blocks were machined to a good flat surface. The mounting was so arranged that four grooves could be obtained on each block, for different loadings. The initial reading of the dial gage was recorded at the start of the test. The readings changed rapidly during the first few minutes of the test, due to the rapid wearing away of the specimen. As the test proceeded, the area of contact widened and the rate of sinking decreased, reaching a nearly zero value at the end of 36 hr. The dial gage was employed to determine when this constant state had been reached. A variation in the dial gage reading of 0.0001 in. was equivalent to 0.00002 in. sinking of the test blocks. The total variation in the reading of the gage had a limited significance, since its initial reading depended on the depth of machine-tool marks on the surface of the blocks.

When the steady state was reached, a liquid film of oil obviously separated the rubbing surfaces. The minimum thickness of this film was just sufficient to separate the irregularities on the block from those of the shaft. The width of the groove worn in the block was such that the hydrostatic pressure created

[1] Associate Professor, Department of Mechanical Engineering, Columbia University. Mem. A.S.M.E. Mr. Karelitz was born in Russia in 1895 and received degrees in naval architecture and mechanical engineering from the Imperial Polytechnic Institute at Petrograd in 1918. For three years he was special engineer with the Waterways of Communication in Russia. He came to the United States in 1922 and has since been connected with the Westinghouse Electric & Manufacturing Company in the capacities of research engineer, manager of the mechanics division of the Pittsburgh research laboratories, manager of the transportation division of the South Philadelphia Works engineering department, and consulting engineer. He began his work at Columbia University in 1930.

[2] Instructor in Civil Engineering, Columbia University. Mr. Kenyon holds the degrees of A.B. from Syracuse University and B.S. and Met.E. from Columbia University. In 1916 he had charge of inspection of munition steel with the British War Mission. In 1918 he entered the employ of the Carnegie Steel Company in the manufacture of electric-furnace steel. In 1923 he was employed by Columbia University as testing engineer and has recently been appointed instructor in civil engineering. Mr. Kenyon is a member of the British Institute of Metals, the American Society for Testing Materials and the Electrochemical Society. He is a licensed professional engineer in New York State. He is the author of several technical treatises published by the A.S.T.M.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Special Research Committee on Lubrication for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

in the clearance between the surface of the groove and that of the shaft balanced the load on the block. The clearance was naturally wedge-shaped, as shown in Fig. 3.

The width a of the grooves worn in the test blocks varied from 0.020 in. to 0.060 in., depending on conditions. The corresponding values of angle θ were 3.7 deg to 10.9 deg. The formulas available for the load-carrying capacity of films between

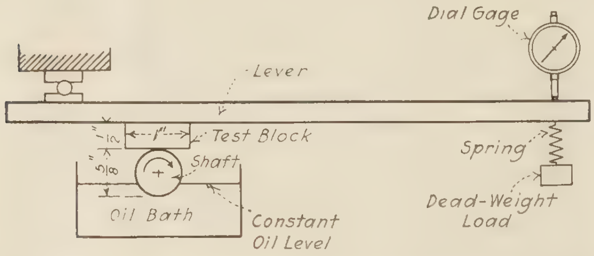

Fig. 1 Sketch of Testing Machine

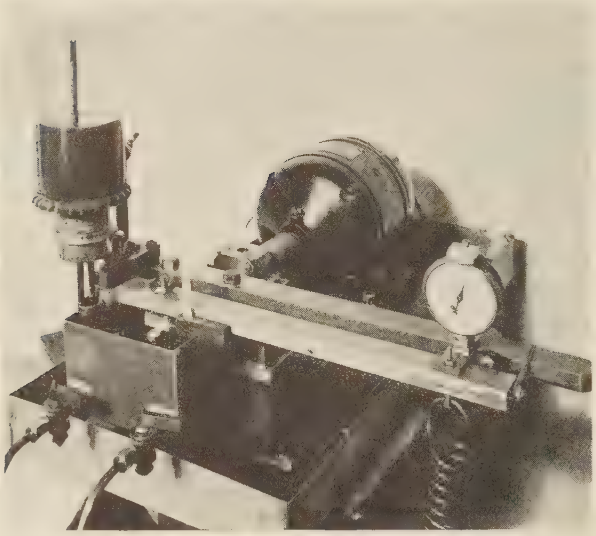

Fig. 2 The Testing Machine

flat surfaces should therefore apply with good accuracy to the films in the groove. The ratio of length to width was so large that the effect of side leakage could be neglected. Boswall (2) gives for the load-carrying capacity of a flat film

$$W = D \times \frac{6\mu\, U\, a^2\, L}{h_o^2} \qquad [1]$$

where W is the total load, lb; U is the peripheral velocity of the journal, in. per sec; a, as shown in Fig. 3, is the groove width, in.; L is its length, in.; h_o is the minimum film thickness, in.; μ is the absolute viscosity of the oil, lb-sec per in.^{2}; and D is a coefficient depending on the angle between the surfaces, i.e., on the ratio h_e/h_o (Fig. 3). According to Boswall the values of D are as follows:

h_e/h_o =	1.7	2.0	2.5	3.0
D =	0.0246	0.0265	0.0263	0.0246

The value of D varies but little for this range of h_e/h_o, the practical values of h_e/h_o being probably within the range. The value of $D = 0.026$ was therefore taken to hold for all test conditions. The viscosity $\mu = (1.45 \times 10^{-7})Z$, where Z is the viscosity in centipoises; $U = [\pi \times (^5/_8) \times (N/60)]$ in. per sec, where N is the speed of the motor, rpm. These values may be substituted into Equation [1], so that

$$h_e = 0.0000272 \sqrt{\frac{Z\, N\, L}{W}} \times a \qquad [2]$$

Equation [2] is good only for the journal of $^5/_8$ in. diameter.

The width a of the groove was measured with a micrometer microscope after removal of the test block from the machine. The width a was taken as the arithmetic mean of five values measured at equidistant points along the groove. The width a varied somewhat, largely due to slight inaccuracies in machining the flat faces on the test blocks.

Materials Tested

The shaft was of chrome-nickel steel of the following analysis: Carbon, 0.26 per cent; manganese, 0.74 per cent; phosphorus, 0.011 per cent; sulphur, 0.027 per cent; silicon, 0.14 per cent; chrome, 0.91 per cent; and nickel, 0.29 per cent. It had a good shop finish. No efforts were made to give it a high polish. During the numerous preliminary runs, however, the surface of the shaft became rather smooth. The accuracy of turning was satisfactory; the vibration at the end of the loading lever was found

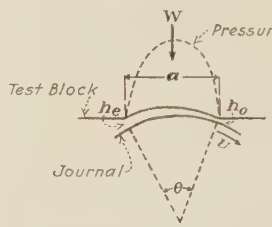

Fig. 3 Form of Oil Film Between the Journal and the Test Block

to be from 0.0006 in. to 0.0008 in., corresponding to only from 0.0001 in. to 0.0002 in. out of true on the test journal (5:1 ratio).

After several preliminary runs, test blocks were prepared of four typical bearing alloys, as shown in Table 1. The molds were built up of steel plates, and the metal was cast into cavities of $1 \times 1 \times ^1/_2$ in. The photomicrographs of the samples showed that the castings were overchilled.

TABLE 1 BEARING MATERIALS USED

Alloy no.	1	2	3	4

S.A.E. 30 oil, with the following viscosities, was used in the tests

Temperature F	80.5	100	120	160	210
Saybolt viscosity, sec	909	483	273	117.2	63.4
	779	424	252	109.7	61.1

The points fall on a straight line in the A.S.T.M. viscosity-temperature chart, which was used for finding the viscosities at running temperatures. The specific gravity of the oil was found to be

Temperature, F	60	85	120	180
Specific gravity	0.8775	0.8745	0.8705	0.8625

The temperature of the test block was measured with a thermocouple during the preliminary runs, and found to be 2 deg higher than the temperature of the oil in the bath. It was assumed that the average temperature of the oil in the oil film was 3 deg higher than the oil-bath temperature.

After each run the oil was changed, and the bath and shaft carefully cleaned, in order to eliminate the effect of bearing material ground off during the previous run.

[a] Speed estimated, in absence of readings, at end of text.

Test Results and Values of h_o

As mentioned previously, the duration of each test was about 48 hr; the test blocks stopped sinking at the end of 36 hr after a viscous oil film had been established between the journal and test block. Typical curves of block sinking plotted against time are shown in Fig. 4. The corresponding temperatures of the oil bath and ammeter readings are also shown in Fig. 4. Each block was tested under loads of 20, 40, and 60 lb, a separate groove being worn in the surface for each load. This eliminated the probable structure variation in different test blocks of the same material.

The observations of the test results together with the computed values of the minimum film thickness h_o are given in Table 2.

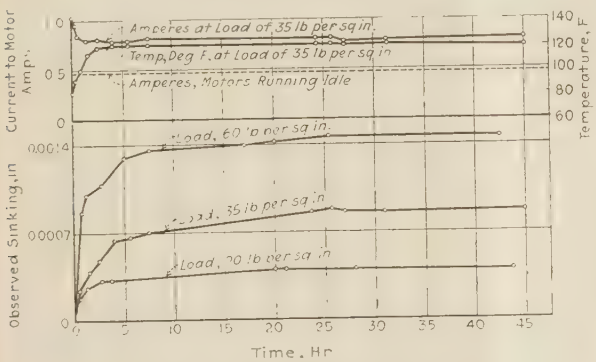

Fig. 4 Rate of Block Sinking, Power Requirements, and Oil Temperatures

It seems that, within the limits of experimental error, the film thickness h_o did not change for any one metal, irrespective of the load on the bearing block. However, the values of h_o did change from metal to metal. The scattered results obtained with the lead-copper alloy were probably caused by the nonuniformity of the material in the specimen, this alloy being rather difficult to cast.

As a matter of record, and to indicate how far values of h_o may vary for different blocks of the same chemical composition, the observations made during the preliminary runs with the various metals are given in Table 3. The oil used was the same as for the test runs. The babbitts show a good correlation between the preliminary runs and the regular tests. The bronze samples show a wider divergence, particularly the leaded copper. It should be remembered that castings of the latter metal, which have been poured at different times, may vary considerably in structure.

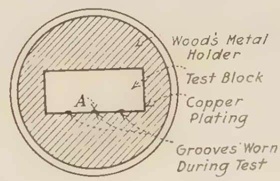

Fig. 5 Method of Mounting the Test Pieces for Polishing

Contact Surface of Bearing Metal

The hydrodynamic theory of lubrication maintains that the bearing metal should wear until the state is reached when the film thickness is equal to the combined height of protrusions on the rubbing surfaces. Therefore, photomicrographs were taken of the cross sections of the bearing blocks near the rubbing surface. The purpose was to observe the actual height of the protrusions and compare these with the computed values of h_o, but to achieve this a magnification was required beyond the power of ordinary microscopes. Fortunately, the assistance of the Bell Telephone Laboratories could be secured, and F. F. Lucas and R. M. Sample were willing to prepare and examine the surface structure of the sections of the test blocks, using the instrument which was described briefly in *Mechanical Engineering* (3).

The polishing of a sample for study under a microscope presents particular difficulties if the structure at the cross-sectional edge is in question. This is due to the fact that even with most careful polishing the edges are rounded off. The focusing of the microscope on the edge is thus interfered with. In this case, the samples were copper plated in order to protect their surfaces, then mounted in Wood's metal for convenience of handling, and the cross section of the sample was carefully polished. The mounting is shown in Fig. 5. Even with these precautions, the polished surface could be obtained reasonably flat at the edge only when the material of the test piece was approximately of the hardness of the copper plating; the surface was slightly rounded, however, with materials appreciably softer than the copper plating. Therefore, it was possible to obtain good photographs of the bearing-bronze test piece; however, the babbitt test pieces were rounded off. The copper-plating

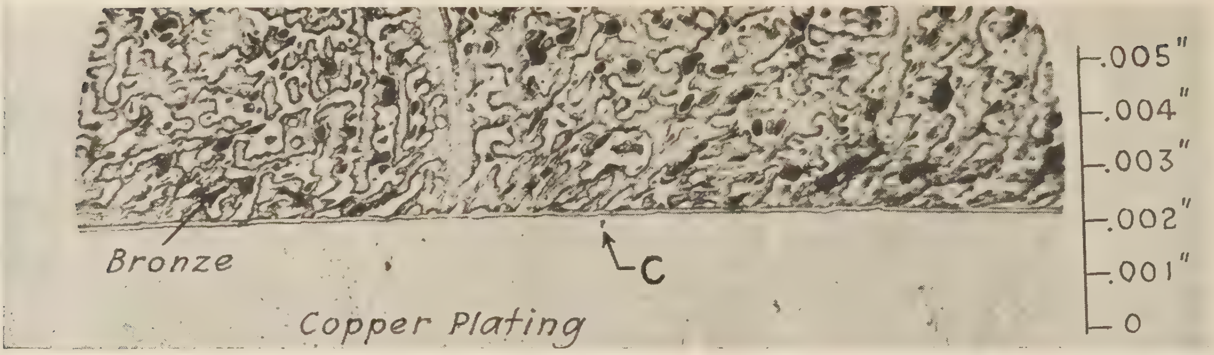

Fig. 6 Surface Structure of Bronze Test Piece, ×300

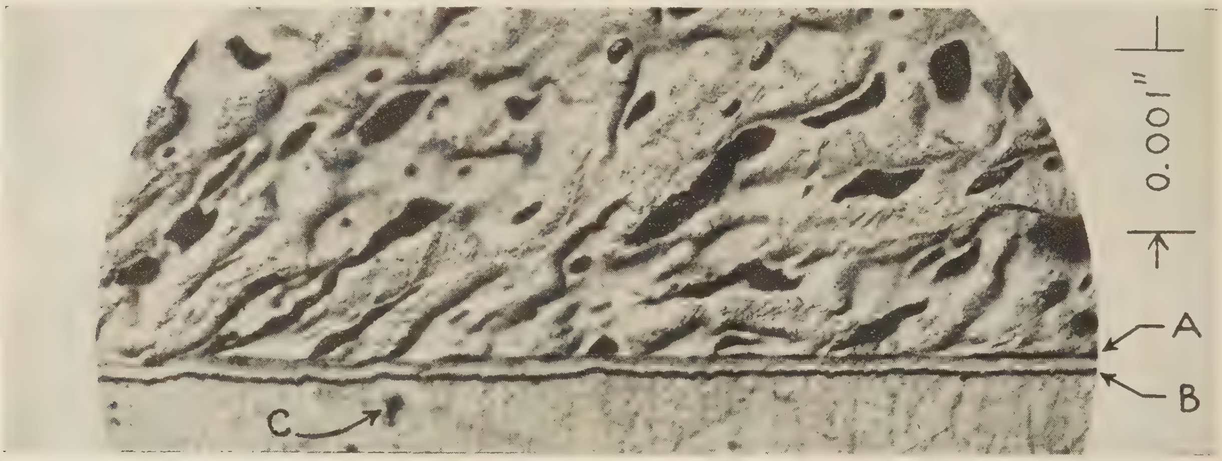

Fig. 7 Surface Structure of Bronze Test Piece, ×1000

could probably be replaced by a softer protective coat, but further work on the subject was not warranted at the time.

Figs. 6, 7, and 8 show the cross section of the bronze test block at the surface of a groove, that is, at point A shown in Fig. 5. The respective magnifications of the three original photographs were 300, 1000, and 4000 diameters. The film-like appearance of the plating at the surface of the bronze was due to the employed technique of copper plating: approximately 0.0001 in. was put on with extreme care, the process of plating was then speeded up. The sharp line B in Fig. 7 is merely the line of demarcation of the two copper platings, while line A is the trace of the bearing surface, of interest for this investigation.

The pinhole C in the copper plating was used for identification of location in the Figs. 6, 7, and 8, so that the structure of the bronze at the bearing surface may be studied conveniently under the three magnifications. Fig. 8 permits direct measurement of the unevenness of the bearing surface. The height of excrescences was found to be 0.000043 in., which compares well with the computed value of h_o = 0.000035 in. for the bronze test piece. Of course, the height of the excrescences on the surface of the steel journal was not known.

Unfortunately, the babbitt test pieces could not be investigated with the same positiveness; and data for comparison of measured height of unevenness with computed values of h_o could not be obtained for the four different materials. Fig. 9 shows the cross section of the test block of tin-base babbitt at the surface. The magnification is the same as in Fig. 8, that is, 4000 diameters. The excrescences seem to be of the same order as in the bronze. It may be noticed that the lens was focused on the edge of the cross section, the surface further inward being out of focus. This was due to the mentioned rounding of the test piece during polishing.

Mechanism of Running In the Bearings

Figs. 6, 7, and 8 give an insight into the mechanism of running in. At the beginning of the experiment, the metal of the test block was subjected to an excessive pressure, much higher than those existing in actual bearings. However, after the test had progressed 2 or 3 hr the pressures on the working surface of the grooves were comparable to those in heavily loaded bearings. At the end of the test the pressures ranged under various conditions from 600 to 1500 lb per sq in. Taking into consideration that in ordinary bearings, while they are run in, the load is carried to a large extent by the high spots of the bearing surface, the unit pressure upon these high spots must be rather great. It may well be assumed that the phenomena at these spots resemble closely the wearing in of the test blocks in the experiments described here.

Figs. 6, 7, and 8 show distinctly that the crystals of the bearing metal were mechanically distorted by the action of the shaft. The drag effect upon the metal was rather uniform over the whole surface of the groove, penetrating to a depth of approximately 0.0015 in. No cracks were apparent; the crystals flowed into their oblique position rather than being crushed into it. In addition to the smearing action, the shaft ground off the surface crystals; the combination of the working and abrasion gave the mirror-like finish characteristic of a run in surface of a bearing.

Fig. 9 reveals a different situation in the case of tin-base bab-

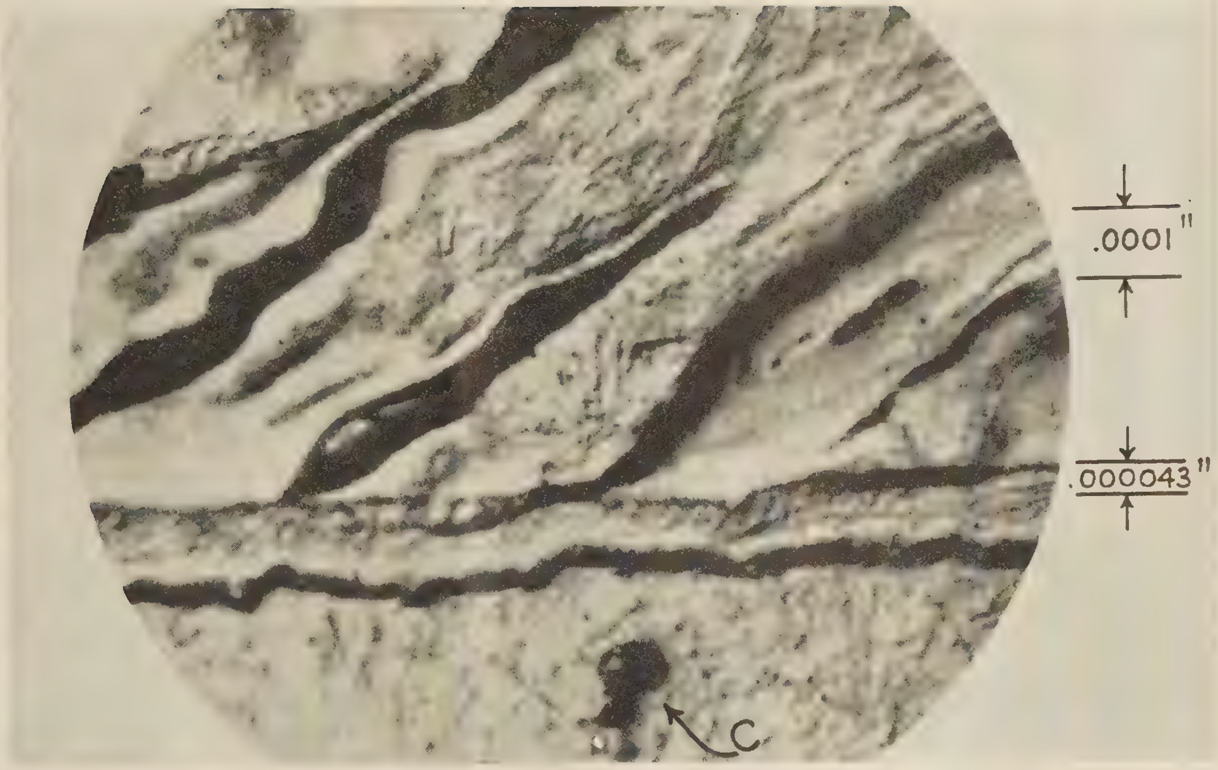

Fig. 8 Surface Structure of Bronze Test Piece, ×4000

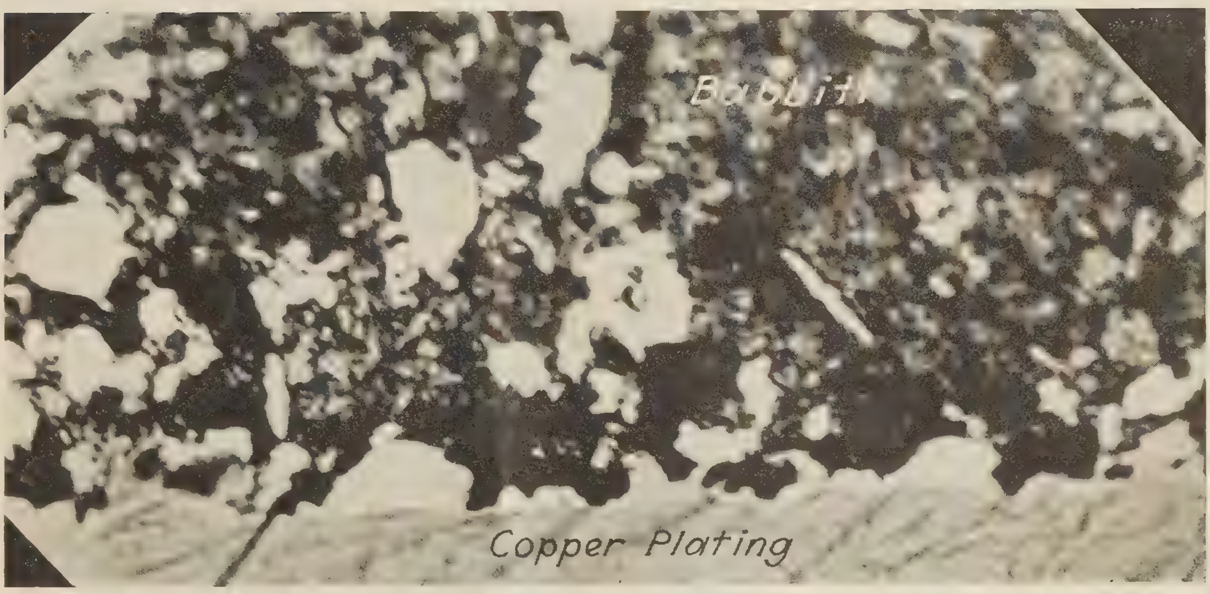

Fig. 9 Surface Structure of Tin-Base Babbitt Test Piece, ×4000

bitt. This might be expected, in view of the radically different constitution of babbitts and bronzes. A tin-base babbitt consists of an eutectic matrix into which crystals of tin-antimony and copper-antimony are imbedded. The crystals apparently give the metal its strength. At elevated temperatures the eutectic becomes comparatively soft and flows easily, thus being responsible for the loss of Brinell hardness. The eutectic becomes mushy at a temperature approaching 310 F when the babbitt may be wiped in the bearing (4). Accordingly, instead of distortion and abrasion of the metal, as was the case with bearing bronze, Fig. 9 shows the eutectic worn away, and the hard white crystals of tin-antimony left behind, providing a pavement on the surface of the babbitt. The crystals are partly crushed and partly abraded. Fig. 9 does not permit measuring the uneven-

ness of the surface, but it may be judged to be of the same order as that of the bronze.

A sample of the lead-base babbitt was also prepared and examined. This material was still more difficult to polish than the tin-base babbitt, and satisfactory photographs could not be obtained. However, examination did show a mechanism of running in quite similar to the one in Fig. 9.

Bowden and Ridler (5) have found that under conditions of dry friction, as well as greasy friction, individual particles on the rubbing surfaces may be heated to extremely high temperatures. With surfaces of Wood's metal they measured temperatures up to the melting point of the metal, thus indicating that the microscopic protrusions actually were liquefied and carried away. With copper and copper alloys they observed temperatures up to 1000 C. This heating was distinctly a surface phenomenon, the bulk of the bearing not showing a noticeable temperature rise. This information, when applied to the tests described herein, explains the flowing of the bronze, as well as the melting of the eutectic matrix at the babbitt surface. The melting temperature of the tin-antimony crystals is about 470 F, i.e., considerably higher than that of the eutectic.

The described mechanism of running in may account for the fact that a thinner oil film was observed with bronze than with tin-base babbitt. It would lead also to the conclusion that lead-base babbitt wears in to a rougher surface than tin-base babbitt. It is also natural to expect that leaded bronze, consisting of a copper-lead alloy with globules of lead entrapped mechanically in the alloy, should wear to a surface not as smooth as the bearing bronze, as was actually observed. On the other hand, one would anticipate its surface to be not much rougher than with babbitts, since experience shows that the leaded bronzes perform as well as the babbitts in automobile bearings.

The running in characteristic of a bearing metal is significant because bearings lined with the smoother metal should be able to carry heavier loads on a viscous film, barring the effect of mechanical or temperature distortion. This means that with the same oil viscosity, radial clearance, and speed, the rougher bearing will enter the semifluid range of friction at a lighter load than the smoother bearing would. It must be remembered, of course, that the experiments reported here are not sufficient to compare definitely different bearing metals. Additional tests are needed in order to formulate a reliable basis for judging running in qualities of various bearing metals.

Comparison With Tests on Running In Bearings

The observed values of h_o can be conveniently compared with values derived from the experiments by McKee on the effect of running in small bearings (6). McKee measured the total friction torque in a set of four bearings carried in one frame, mounted on a common shaft of 1.25 in. diameter. Two series of tests were reported: The first was with a set of bearings of clearance ratio $\delta/D = 1/450$, while bearings with a ratio $\delta/D = 1/2250$ were used in the second series. All bearings were 1.25 in. long. The friction was measured at intervals, while the bearings were gradually run in. McKee stated: "The first five runs of the first test were completed with no running in between runs, the effect produced by each run, in itself being sufficient to show a change in the curve for the succeeding run. In connection with all subsequent runs, however, some running in was done between runs at a value of ZN/P below that at the point of minimum friction for the preceding run." The duration of each run was approximately 2 hr.

The ZN/P values at the points of minimum friction for the consecutive runs are given in McKee's paper (6). It may be assumed that these points of minimum friction, or more correctly, the points of minimum coefficient of friction, are the points where the viscous film in the bearing breaks down, i.e., when the first metal-to-metal contact occurs. This is the condition which existed in the films under the bearing blocks described in the present paper. The bearings used by McKee were of tin-base babbitt (Sn, 85; Cu, 7.5; Sb, 7.5); the shaft was made of high-carbon-tungsten tool steel. The film thickness in the bearings, after running in, should, therefore, compare with the values obtained with the tin-base babbitt block. The film thickness at the points of minimum friction in the bearings tested by McKee can be determined using the charts computed by Dennison (7) for the case of high eccentricity, i.e., low values of ZN/P. Dennison gives the film thickness as $h_o = (1/m) \times (\delta/2)$, where $(\delta/2)$ is the radial clearance. The values of h_o at the points of minimum friction for several consecutive runs are given in Table 4. The minimum film thickness obtained with the bearings well run in are of the same order as those obtained with the test block. The latter fall between the values h_o computed for the two sets of McKee's bearings.

Effect of Lubricant on the Running In

In order to observe whether physical properties of the lubricant play an appreciable part in the mechanism of running in, a light commercial-stock oil was obtained from a source different from the oil used in the tests reported in this paper. In the following, this light oil will be denoted by letter B, while the oil which was used earlier will be called oil A. The viscosity of the oil B was

Temperature, F	100	210
Saybolt viscosity, sec	68.0	36.6

while its specific gravity was found to be

Temperature, F	60	75	120	180
Specific gravity	0.8759	0.8699	0.8593	0.8351

Another sample of oil B was received mixed with 1 per cent of butyl stearate by volume, an ingredient improving the oiliness of a lubricant.

Two bearing blocks, one of tin-base, the other of lead-base babbitt were used for this test. Babbitt blocks were chosen because their structure was more uniform across the bearing face than that of the bronze blocks. Each block was run with a load of 40 lb. One groove each was obtained with oil A, oil B, and alloyed oil B. The temperatures and corresponding viscosities of the oils are listed in Table 5. The shaft and the test pieces were cleaned carefully with carbon tetrachloride after each run. It was found that the lighter oil produced a decidedly thinner oil film (smaller value of h_o). This would indicate that the lighter oil created a finer polish on the surface of the groove. It should be noted that the 1 per cent butyl stearate apparently did not affect the performance, which was rather unexpected.

Lead-base	heated	182	11.9	0.0912	0.000066	17

The results obtained with the two different babbitts were in satisfactory agreement with each other

The viscosity of the oils being so different, it was possible that the comparatively rough surface obtained with the heavier oil, was caused by debris worn away from the block and carried in the more viscous lubricant. Therefore, an additional test was run with each block, using the oil A, but heating the oil bath by means of an electric element. As shown in Table 5, the viscosity of the lubricant was even smaller than that of the oil B. However, the minimum film thickness changed but slightly.

Illustrations of the eight grooves worn in the two blocks with the different oils are shown in Figs. 10 to 17, inclusive. All the illustrations were made under the same magnification of 20 diameters. Figs. 14 and 15 show clearly the pitmarks produced at the entering edge by the particles worn away and floating in the oil bath. It may be noticed that the groove is smooth at the trailing edge, indicating that the clearance between the shaft and bearing was too small for the particles to pass and was acting as a local filter for the oil. All other grooves, obtained with the oils of lower viscosity, were free from pitting.

Conclusion

The number of tests made with the machine was too small for generalizations, or to permit a definite comparison between the various bearing materials. However, the correlation of the obtained results with those derived from the experiments of McKee (6) is satisfactory. The several observations on individual materials were also rather consistent. The photomicrographs of the bearing cross sections at the rubbing surface showed excrescences comparable with the observed minimum film thickness, under conditions analogous to those existing in bearings at the point of transition from viscous to semifluid lubrication. Therefore, it was deemed that the information might be of value to engineers interested in the performance of bearings or in their lubrication. The authors take this opportunity to express their appreciation of the helpful cooperation obtained from F. F. Lucas and R. M. Sample of the Bell Telephone Laboratories.

Operating-Cost Analysis of Electrified Oil Lines

By W. H. Stueve,[1] Oklahoma City, Okla.

The author submits data on the capacity and power requirements when pumping oil through two 10-in. pipe lines, 191.4 and 126 miles long, respectively. The first of these lines has three stations, located at approximate distances of 60 miles, each of which is equipped with plunger pumps handling 35,000 bbl of crude oil per day at a pressure of 800 lb per sq in. The second line has four stations, located at approximate distances of 32 miles, each of which is equipped with centrifugal pumps handling 40,000 bbl of crude oil at a pressure of 800 lb per sq in. The author gives the relative efficiencies of the centrifugal and plunger pumps and determines the overall pumping charges for each line. He calculates the operating costs if oil engines were installed as prime movers instead of electric motors. Calculations are also made to show the effect on operating charges if larger diameter pipe were installed, and if the pumping stations were spaced farther apart than in the existing lines.

The large volumes of crude oil offered to the market through the discovery of the Seminole field in Oklahoma and the West Texas and East Texas fields, caused widespread expansion of pipe-line facilities of the major pipe-line companies from 1926 to 1930. At the beginning of this expansion period it was common practice to use electric motors for small gathering pumps and oil engines in the larger main-line pumping stations. About 1927 the first motor-driven centrifugal oil-line pumps were considered for use in this industry. Today there are 200,000 hp of motor-driven pumps in this kind of service, representing approximately 20 per cent of the total installed horsepower for main-line pumping stations.

Before any data were obtainable relative to the performance of stations using electrically driven pumps, design engineers were prone to use theoretical values of pressures, viscosities, pump efficiencies and other factors which influence the cost of pumping oil. Today, after motor-driven centrifugal pumps have been in use for nearly 7 years, and motor-driven plunger pumps have been in use for nearly 5 years, information regarding the performance and power requirements of such units is meager and difficult to obtain, and when such meager information is available it is usually restricted to private use. However, reliable data of this nature have been obtained by the author from several pipe-line companies. These data show the average daily delivery in barrels per day for each month, and electric energy purchased per month at stations where oil is pumped through a 10-in. pipe line by plunger pumps driven by slow-speed induction motors, and at other stations where oil is pumped through a 10-in. pipe line with centrifugal pumps driven by relatively high-speed induction motors.

Therefore, the scope of this paper will be to determine the relative efficiencies of these centrifugal and plunger pumps, and to determine the overall pumping charges, considering the total investments in the several types of pumping stations. An effort will be made also to calculate the operating costs if oil engines were installed as prime movers instead of electric motors. Calculations will also be made to show the effect on operating charges for the entire pipe lines had larger diameter pipe been installed, and if pumping stations had been spaced farther apart than in the existing lines.

For the sake of simplicity, and to avoid disclosing the actual identity of the source of information, the pipe line equipped with plunger pumps will be known as Alpha Pipe-Line Company. This company utilizes three 600-hp stations, called A, B, and C, respectively, to pump about 35,000 bbl of crude oil per day at 800 lb per sq in. through a 10-in. pipe 191.4 miles long. The crude oil pumped has an average viscosity of about 50 S. sec U. and an A.P.I. gravity of 35 deg. There is a distance of 58.6 miles between stations A and B, 69.2 miles between stations B and C, and 63.6 miles between station C and the end of the line. The elevations of stations A, B, and C are 262, 343, and 103 ft, respectively. The line ends at an elevation of 52 ft.

The pipe line equipped with centrifugal pumps will be known as the Omega Pipe Line Company. This company utilizes four 800-hp stations, called W, X, Y, and Z, respectively, to pump 40,000 bbl of crude oil per day at 800 lb per sq in. through a 10-in. pipe 126 miles long. The crude oil pumped has an average viscosity of about 100 S. sec U. and an A.P.I. gravity of 30 deg. There is a distance of 29.5 miles between stations W and X, 29 miles between stations X and Y, 35 miles between stations Y and Z, and 32.5 miles between station Z and the end of the line. The elevation of stations W, X, Y, Z, and the end of the line are 915, 997, 1075, 1017, and 875 ft, respectively.

Comparison of Pump Efficiencies

Fig. 1 shows the average daily volume pumped, and the total electric energy in kilowatthours consumed each month by the three 600-hp plunger-pump stations A, B, and C of the Alpha Pipe-Line Company from October, 1931, to January, 1936.

Fig. 2 shows the average daily volume pumped, and the total electric energy in kilowatthours consumed each month by the four 800-hp centrifugal-pump stations W, X, Y, and Z of the Omega Pipe Line Company from January, 1929, to January, 1936.

From Figs. 1 and 2 may be noted the wide fluctuation in average daily deliveries from month to month during the years covered, and with particular significance the fluctuations in electric energy required are noted. In all cases when the most economical

[1] Commercial Department, Oklahoma Gas and Electric Company. Mr. Stueve was graduated from Ohio State University in 1909, with degrees of E.E. and M.E. During the War he served as engineer officer in the transport force with the rank of ensign and lieutenant (JG) in the United States Navy. For ten years he was a consulting engineer in Oklahoma for municipal power and water plants. In his present position he is in charge of electric-power sales to the petroleum industry for the Oklahoma Gas and Electric Company. Mr. Stueve was awarded the professional degree of mechanical engineer in 1936 by Ohio State University. He is a registered professional engineer in Oklahoma.

Contributed by the Petroleum Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers held at Dallas, Texas, June 15 to 20, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

use is made of electrical power, the energy consumed by all such stations, expressed in per cent of the total electrical energy required to pump at the maximum design rate, is equal to the capacity factor expressed in per cent of maximum capacity raised approximately to the 2.2 power, as developed later in Fig. 6.

This rule will follow when specific months are selected from Figs. 1 and 2. The rule will also follow approximately when the annual average deliveries are considered for years taken as a whole.

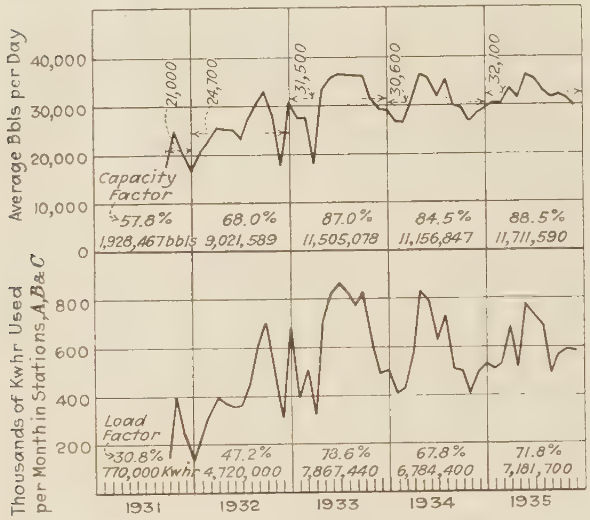

Fig. 1 Pumping Capacities and Energy Requirements of the Alpha Line

Table 1 is prepared from specific typical months to determine the pump efficiencies at various rates of pumping. The energy requirements listed in Table 1 are in kilowatthours per barrel pumped per 100 miles, in order to make the results comparable for both pipe lines, since the stations on the Alpha line are about 64 miles apart, while those on the Omega line are spaced about 32 miles apart.

The computed results shown in Table 1 for the Alpha pipe line equipped with duplex double-acting plunger-pump stations, indicate the very high average mechanical efficiency of 98 per cent for the pumps when operating at their designed maximum ratings using both plungers. In the case where 25,000 bbl were pumped per day, one of the duplex pumps was operated with one plunger disconnected from the crosshead, and the overall mechanical efficiency dropped to an average of 85 per cent for this condition. Again note that when only one pump was required as in January, 1932, pumping 17,500 bbl per day, its maximum capacity, against fairly high pressures, the mechanical efficiency again was of the order of 96 per cent, or that achieved when both pumps were operated at high design pressures. In this case station A pumped through stations B and C, that is, the entire length of the line or 191.4 miles.

In April, 1933, the same average volume of 17,500 bbl per day was pumped, but each of the three stations, A, B, and C was operated, building up pressures at each of the stations of only one third of the total pressures or perhaps 220 lb per sq in., and the mechanical efficiency dropped down to 55 per cent. This method of pumping is very uneconomical, since the kilowatt-hours per barrel per hundred miles was increased to 0.32, or approximately two and one half times the energy required had the pump of station A been permitted to pump the entire distance of 191.4 miles against the high design pressure of about 800 lb per sq in.

Referring to Fig. 3a, note that the points on the curve for kilowatthours per barrel per 100 miles for selected months very closely approximate the points for yearly averages of kilowatthours per barrel per 100 miles taken from Fig. 1, tending to lend considerable merit to the mechanical efficiency of plunger pumps as given in Table 1 for the Alpha line.

The computed results in Table 1 for the Omega pipe line equipped with centrifugal pumps, indicate that the pump efficiency when operating at a maximum capacity of 40,000 bbl per day is about 60 per cent, and that when the discharge is throttled for lower capacities the efficiency points are lower, as would be expected. In this line, two pump units are used in series until the capacity drops to about 70 per cent of the maximum, at which point the line pressure is only one half that of the line pressure required for 100 per cent capacity and, therefore, one pump unit will deliver the required pressure. Note, in Fig. 3b that when this condition prevails, namely, when the average daily pumping requirements are only 70 per cent of the maximum, or 40,000 bbl per day in this case, the efficiency of the single pump unit is 55 per cent, but no doubt the mechanical efficiency would be higher if the pipe line did not act as a throttle to the pump. This can readily be illustrated by extending the efficiency curve for the single pump unit in Fig. 3b to the point where 40,000 bbl would be pumped per day, at which point the single pump unit would show an efficiency of 68 per cent, the original factory guarantee.

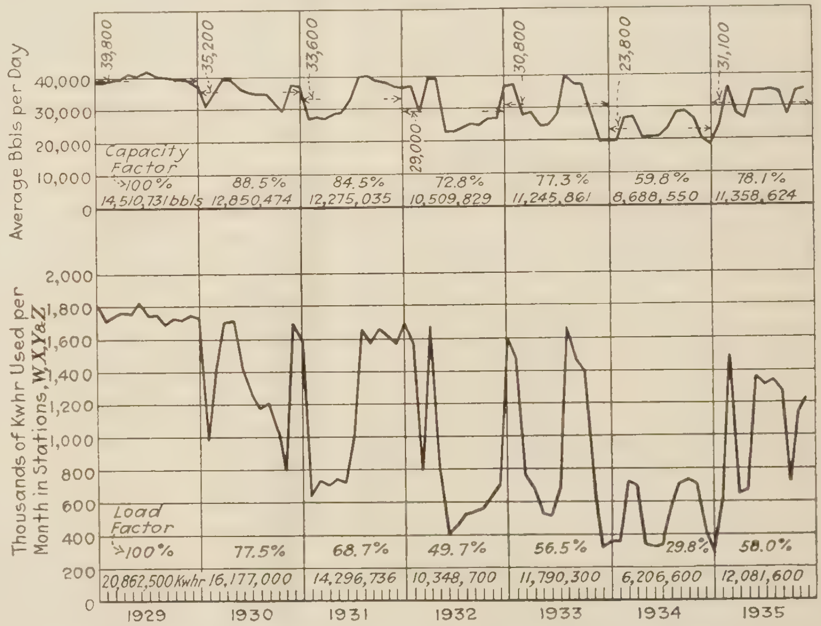

Fig. 2 Pumping Capacities and Energy Requirements of the Omega Line

Also, it may be said that the mechanical efficiencies of the centrifugal pump as derived from data given in Table 1 may not be exactly fair to the centrifugal pump, since the mechanical

[a] The 10-in. Alpha line is equipped with plunger pumps and is 191.4 miles long.
[b] Station *A* pumped to destination, a distance of 191.4 miles.
[c] Stations *A*, *B*, and *C* in operation.
[d] The 10-in. Omega line is equipped with centrifugal pumps and is 126 miles long.
[e] Pump driven by a 400-hp motor operated at stations *W*, *X*, *Y*, and *Z*.
[f] Pump driven by a 400-hp motor operated at stations *W* and *Y* only.

efficiency depends on knowing the fluid or theoretical horsepower, and this factor cannot be positively calculated from the data submitted unless more information on the actual pumping pressures, under all conditions of capacity, is made available at each of the stations. Again note from Fig. 3*b* that the points showing the annual average kilowatthours per barrel per 100 miles fall very close to the curve for kilowatthours per barrel per 100 miles for specific months, tending to lend considerable merit to the pump mechanical efficiencies given in Table 1 for centrifugal pumps in the Omega line.

After having determined the approximate energy required to pump given volumes of crude oil through several pipe lines, and having determined the mechanical efficiency of the two accepted types of plunger and centrifugal pumps, the author deemed it of importance to show the actual costs of operation, after taking

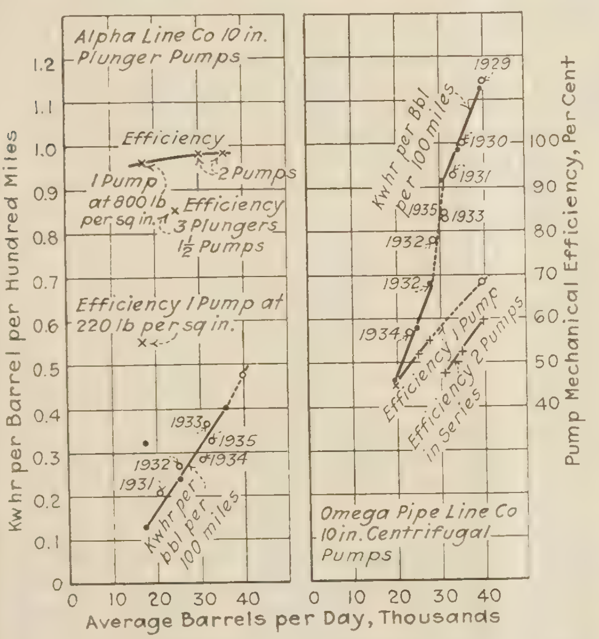

FIG. 3 GRAPHIC REPRESENTATION OF RESULTS LISTED IN TABLE 1

into account all charges, had the Omega line been equipped in 1928 with plunger pumps driven with 350-hp, 585-rpm induction motors.

COMPARISON OF PUMPING COSTS

Had the Omega pipe line been equipped with plunger pumps,

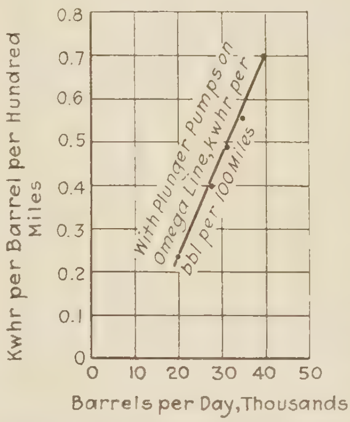

FIG. 4 ENERGY REQUIRED BY PLUNGER PUMPS OPERATING ON THE OMEGA LINE

the energy required by such pumps would be in inverse proportion to the respective determined overall (motor and pump) efficiencies given in Table 1 and shown graphically in Fig. 3. The mechanical efficiencies plotted in Fig. 3 are for both types of pumps but for different capacities, and are taken from actual data.

Fig. 4 shows the energy which would be required if the Omega line were equipped with plunger pumps, and pumping the same type of crude oil, that is, oil with a viscosity of 100 S. sec U. and an A.P.I. gravity of 30 deg.

In 1928 centrifugal pumps with speeds of 3600 rpm were not very well received by pump designers. Since that time performance and cost data on these pumps have become available, and the comparison of pumping costs outlined in this paper was selected because the author believes such a comparison will be of interest to design engineers and will enable them to make the proper selection of pumps at this time.

The pumping stations on the Omega line, equipped with three centrifugal pumps, each driven by a 400-hp motor running at 1760 rpm, have a capacity of 40,000 bbl per day. This capacity is delivered with two pumps in series at a pressure of about 800 lb per sq in. One 400-hp unit is for stand-by purposes. The total cost of each station was approximately $70,000.

If plunger-pump stations were installed on the Omega line, they would probably be equipped with three $5^1/_2 \times 24$-in. duplex double-acting pumps geared to 350-hp motors running at 585 rpm. Each of these pumps would be capable of delivering 20,000 bbl per day, or with two pumps in parallel, the capacity would be 40,000 barrels per day, this latter volume being the same as the capacity of the two centrifugal pumps in series. One 350-hp unit would be used for stand-by purposes. The total cost of such a station is estimated at $110,000.

Table 2 has been prepared to show the annual operating costs of plunger-pump stations on the Omega line. The theoretical costs were determined from Figs. 2 and 4. The cost per kilowatthour per barrel per 100 miles for pumping oil with plunger pumps was taken from Fig. 4, while the average annual volume

TABLE 2 ANNUAL OPERATING CHARGES FOR THE OMEGA PIPE LINE OVER A PERIOD OF 7 YEARS, AT THE ANNUAL AVERAGE RATES SHOWN IN FIG. 2

(a) Theoretical costs for plunger pumps and induction motors							
Year	1929	1930	1931	1932	1933	1934	1935
Average rate from Fig. 2, bbl per day	39,800	35,200	33,600	29,000	30,800	23,800	31,100
Operating costs:							
Fixed charges: 8 per cent on $440,000	$ 35,200	35,200	35,200	35,200	35,200	35,200	35,200
Labor: 5 men @ $675 per month per station	$ 32,400	32,400	32,400	32,400	32,400	32,400	32,400
Electric power: average kwhr per bbl per 100 miles from Fig. 4 × 1.26 @ 1c per kwhr	$129,000	95,000	84,000	58,600	69,000	33,800	71,600
Maintenance: 50c per hp per year	$ 2,100	2,100	2,100	2,100	2,100	2,100	2,100
Total operating costs	$198,700	164,700	153,700	128,300	138,700	103,500	141,300
(b) Actual costs for centrifugal pumps and induction motors							
Operating costs:							
Fixed charges: 8 per cent on $280,000	$ 22,400	22,400	22,400	22,400	22,400	22,400	22,400
Labor: 5 men @ $675 per month per station	$ 32,400	32,400	32,400	32,400	32,400	32,400	32,400
Electric power: actual kwhr from Fig. 2 @ 1c per kwhr	$208,625	161,770	142,967	103,487	117,903	62,066	120,816
Maintenance: 50c per hp per year	$ 2,400	2,400	2,400	2,400	2,400	2,400	2,400
Total operating costs	$265,825	218,970	200,167	160,687	175,103	119,266	178,016
Accumulated savings in favor of plunger pumps, compounded at 4 per cent annually	$ 67,125	124,020	175,467	214,887	260,403	286,766	334,716
Saving per year by using plunger pumps	$ 67,125	54,270	46,467	32,387	36,403	15,766	36,716

of oil pumped in the Omega line was taken from Fig. 2. The actual operating costs for the Omega line equipped with centrifugal pumps were calculated from data given in Fig. 2. The actual depreciation charges are omitted in this comparison in order that the retirement period of the more costly pumping stations, if any, can be determined more readily. Fixed charges, therefore, consist only of 6 per cent interest, and 2 per cent taxes and insurance, or a total of 8 per cent.

Referring to Table 2, it is noted that in every year of the 7-year life of this line, plunger pumps operated more cheaply than the centrifugal pumps actually operated. In fact, the difference in pumping-station investment ($440,000 — $280,000) of $160,000 could have been retired in 2.4 years had the high capacity factor of 1929 been maintained in the succeeding $1^1/_2$ years. Actually the plunger pumps would have paid for themselves before the end of the third year. Note that in 1934, with an annual average capacity factor of 60 per cent, the savings accomplished by the theoretical plunger-pump stations are the smallest in the 7-year period. In this case, if 10-years' depreciation were added to both annual operating costs, the costs on the centrifugal-pump stations would equal the costs on the plunger-pump station. Therefore, it may be said that plunger-pump installations operated with electric motors would prove more economical than centrifugal-pump stations in almost all cases, since most pipe lines are installed to operate at relatively high capacity factors, usually in excess of 75 per cent during the first few years of their installed life. This conclusion, however, is not definite or fair to present-day centrifugal pumps.

Most centrifugal oil-line pumps today are equipped with induction motors and operate at approximately 3600 rpm, and efficiencies of 75 to 80 per cent are obtainable with such units when volumes of 40,000 bbl per day and larger are pumped. Thus, if centrifugal pumps with a mechanical efficiency of 75 per cent at the maximum rated volume had been available in 1928, the year in which the Omega pipe line was constructed, the overall efficiency of pump and motor would have been (75 × 94, respectively) or about 70 per cent instead of 56 per cent, as given in Table 1 (b) for maximum volume. This increased efficiency would have resulted in a power consumption of perhaps 20 per cent under that shown in Fig. 2.

The higher-speed units would be cheaper to install than the slower-speed units, the approximate saving being $5000 per station, thus giving a total cost of $65,000 per station. The difference in first cost between a pipe line with four stations equipped with high-speed centrifugal pumps and a pipe line with four plunger-pump stations would be ($440,000 — $260,000) $180,000 instead of $160,000. This would extend the retirement period of plunger-pump stations over high-speed centrifugal-pump stations to 14 years or longer, instead of about 3 years, as given in Table 2 for the slow-speed centrifugal-pump stations.

Note that the accumulated annual savings in Table 2, if compounded at 4 per cent, amount at the end of the 7-year period to $334,716 in favor of installing plunger pumps, which in effect is more than twice the increased cost of plunger pumps over centrifugal pumps.

The use of synchronous motors for oil-line pumping is not discussed in this paper. Although it is true that the synchronous motor inherently has a higher efficiency than the induction motor by perhaps several points, the saving in power cost by using synchronous motors may easily be overcome by the fixed charges on the increased first cost of the synchronous motor, coupled with the fixed charges on increased station cost requiring the installation of a fire wall between the motor and pump.

Operating Costs With Oil Engines Driving the Pumps

This paper has dealt with efficiencies of plunger and centrifugal pumps. However, it would not be complete without showing the pumping costs, if oil engines were used instead of motors. The results of electric operation so far indicate that the plunger-pump installation is cheaper to operate, after all factors of annual operation charges are considered including depreciation for a life of 15 to 20 years, than installations using modern highly efficient 3600-rpm centrifugal pumps, and therefore the comparison between motors and engines will be based on using plunger pumps with oil-engine prime movers, and induction-motor prime movers.

The station equipped with oil-engines for driving plunger pumps will be assumed to have three 350-hp engines operating at 250 rpm, each driving 20,000-bbl plunger pumps. The installation cost of each station is $200,000, including working tanks, cottages, and all necessary auxiliary equipment. The brake energy required to be generated by the oil engines will be assumed the same as the electric energy purchased for the induction-motor plunger-pump stations, less the motor losses. Thus, for the sake of simplicity, the electric energy used by plunger pumps for various capacities as shown in Fig. 4 times 0.90 (the average motor efficiency) will be used as the kilowatt-hours per barrel per 100 miles required by oil engines to perform the same work on the Omega line. Table 3 compares the total pumping charges of stations operated with oil engines and stations operated with induction motors, including the cost of the 10-in. pipe line 126 miles long, station costs and all apparent operating costs for the 7-year period of operation of the Omega line. The figures in Table 3 also allow for depreciation over a 20-year period at 5 per cent per year.

Referring to the results given in Table 3, it is noted that electric-driven plunger pumps operate cheaper than pumps driven by oil engines in all of the 7 years with the exception of the first year (1929), when the capacity factor was 100 per cent. In other words, when the annual pumpings are less than about 90 per cent

TABLE 3 ESTIMATED ANNUAL OPERATING CHARGES FOR THE OMEGA PIPE LINE, USING PLUNGER PUMPS OPERATED WITH BOTH INDUCTION MOTORS AND OIL ENGINES

(*a*) Oil engines to plunger pumps							
Year	1929	1930	1931	1932	1933	1934	1935
Average rate for the year, bbl per day	39,800	35,200	33,600	29,000	30,800	23,800	31,100
Operating costs:							
Interest, depreciation, and taxes 13 per cent on 126 miles of 10-in. pipe line @ $10,500 per mile	$172,000	172,000	172,000	172,000	172,000	172,000	172,000
Depreciation (20 year) 5 per cent on station cost of $800,000	$ 40,000	40,000	40,000	40,000	40,000	40,000	40,000
Interest and taxes 8 per cent of station cost of $800,000	$ 64,000	64,000	64,000	64,000	64,000	64,000	64,000
Labor: 8 men per station @ $1125 per month	$ 54,000	54,000	54,000	54,000	54,000	54,000	54,000
Fuel: average cost per bbl by the year	$ 1.48	1.43	0.93	1.13	0.86	1.26	1.26
Fuel cost: kwhr converted from Fig. 4 to bhp-hr, 600 bhp-hr per bbl, @ average cost	$ 38,000	27,200	16,000	13,300	11,700	8,830	17,600
Lubrication: 5c per 1000 bbl per station	$ 2,900	2,560	2,450	2,100	2,250	1,740	2,270
Maintenance: $2 per hp installed per year	$ 8,400	8,400	8,400	8,400	8,400	8,400	8,400
Total operating costs	$379,300	368,160	354,850	353,800	352,350	348,970	357,870
Cost per bbl pumped, cents	2.61	2.86	2.88	3.35	3.12	4.02	3.14
(*b*) Induction motors to plunger pumps							
Operating costs:							
Interest, depreciation, and taxes 13 per cent on 126 miles of 10-in. pipe line @ $10,500 per mile	$172,000	172,000	172,000	172,000	172,000	172,000	172,000
Depreciation (20 year) 5 per cent on station cost of $440,000	$ 22,000	22,000	22,000	22,000	22,000	22,000	22,000
Additional operating expense taken from Table 2 (*a*)	$198,700	164,700	153,700	128,300	138,700	103,500	141,300
Total operating costs	$392,700	358,700	347,700	322,300	332,700	297,500	335,300
Cost per bbl pumped, cents	2.70	2.78	2.83	3.07	2.95	3.42	2.94

of the maximum capacity of the units, the electric-driven plunger pumps operate cheaper for all prices of crude oil used for fuel in the engines, costing $1.43 per bbl in 1930 to 86 cents per bbl in 1933, provided electric power costs approximate 1 cent per kwhr. The fuel costs used were taken as the average market price of crude during the year, plus 10 cents gathering charge per barrel, plus the tariff for transporting the oil one half the distance in the pipe line.

Since the value of fuel is a variable quantity from year to year, it is interesting to compare the price of electric power for the 7-year period with specific values of fuel oil or crude at $1 and $1.50 per bbl, using the capacity factor achieved during this period. These values are plotted in Fig. 5 in order that proper comparisons can be drawn.

From Fig. 5 it will be noted that electric energy should be sold at an average cost of about 0.9 cent per kwhr during 1929 when the capacity factor achieved was 100 per cent, and the value of crude was $1.48 per bbl. In succeeding years, when the average capacity factor was lower than 100 per cent, the electric power would have demanded a higher sale price for the electric operating costs to equal the engine operating costs. In fact, during 1934, when the capacity factor was about 60 per cent, electric power charges could have been about 2.5 cents per kwhr with fuel or crude costing $1.25 per bbl, the average cost of fuel during 1934.

However, the power was purchased at an average cost of 1 cent per kwhr for the entire 7 years, because each month a high electric load factor was attained in each of the pumping stations, and all electric power is usually sold on the basis of load factor attained during the specific month.

The popular conception of power charges for pipe-line pumping is that the rate per kilowatthour should be a fixed amount on a flat basis to enable electrically driven stations to compete with stations equipped with oil-engine units, and therefore, to disprove this theory, the permissible rates per kilowatthour in cents are shown for the 7 years' operation in Fig. 5. Note that such permissible annual average costs of electric energy in Fig. 5 fall on definite curves for the two values of fuel oil considered.

The cost of electric energy at 1 cent per kwhr, being constant value throughout the 7-year period, cuts the curve of permissible electric-energy cost for both values of fuel oil at a capacity factor of about 90 per cent.

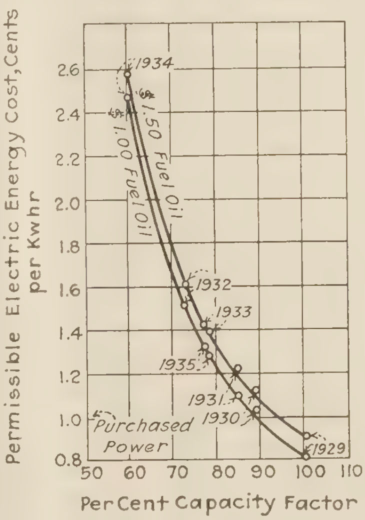

FIG. 5 ELECTRIC-ENERGY COST WHICH WILL PERMIT ELECTRIC OPERATION TO EQUAL OIL-ENGINE OPERATION COSTS

In order that a definite method of determining the actual amount of electric energy required in all pumping stations along a given pipe line for various conditions of capacity can be worked out, the average annual capacity factors for the Alpha pipe line from Fig. 1 and the average annual capacity factors for the Omega line from Fig. 2 are plotted in Fig. 6 against the percentage of maximum electric energy purchased. The curve shown in Fig. 6, drawn as an average between all those points, verifies the assumption made previously, that if the capacity factor expressed as a percentage is raised to the 2.2 power, the resultant percentage will determine the amount of electrical energy required in all stations in terms of per cent of the maximum electric energy required.

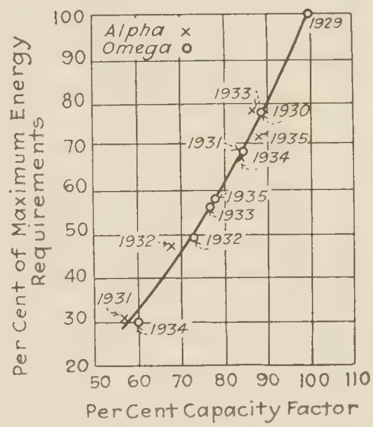

FIG. 6 RELATION BETWEEN CAPACITY FACTOR AND ELECTRIC POWER REQUIRED IN ALL PUMPING STATIONS ON THE ALPHA AND OMEGA LINES

(Per cent maximum electric-energy requirements equals per cent capacity factor raised to the 2.2 power.)

OPERATING COST USING A 12-IN. PIPE

The use of larger pipe diameters and a smaller number of stations has always been considered by pipe-line engineers, but rarely practiced or recommended. Since an attempt was made previously in this paper to determine the actual pumping costs for the 10-in. Omega line with four pumping stations equipped with electrically driven plunger pumps, as given in part *b* of Table 3, a study of comparative costs could readily be made to show the

TABLE 4 ESTIMATED ANNUAL OPERATING CHARGES FOR THE OMEGA PIPE LINE, USING 10-IN. PIPE AND 12-IN. PIPE WITH PLUNGER PUMPS DRIVEN BY INDUCTION MOTORS

(a) Four 700-hp stations pumping through a 10-in. pipe line ($1,765,000 total cost)							
Year	1929	1930	1931	1932	1933	1934	1935
Average bbl per day for the year	39,800	35,200	33,600	29,000	30,800	23,800	31,100
Operating cost:							
Same total costs as shown in Table 3 (b)	$392,700	358,700	347,700	322,300	332,700	297,500	335,300
Cost per barrel pumped, cents	2.70	2.78	2.83	3.07	2.94	3.42	2.95
(b) Two 700-hp stations pumping through a 12-in. pipe line ($1,795,000 total cost)							
Operating costs:							
Interest, depreciation, and taxes 13 per cent on 126 miles of 12-in. pipe line @ $12,500 per mile	$205,000	205,000	205,000	205,000	205,000	205,000	205,000
Interest, depreciation, and taxes 13 per cent on station cost of $220,000	$ 28,500	28,500	28,500	28,500	28,500	28,500	28,500
Labor: 5 men, @ $675 per month per station	$ 16,200	16,200	16,200	16,200	16,200	16,200	16,200
Electric power: kwhr per bbl per 100 miles from Fig. 4 × 0.45 × 1.26 @ 1c per kwhr	$ 57,600	42,700	38,500	26,800	30,800	15,750	31,600
Maintenance: 50c per hp per year	$ 1,050	1,050	1,050	1,050	1,050	1,050	1,050
Total operating costs	$308,350	293,450	289,250	277,550	281,550	266,500	282,350
Cost per barrel pumped, cents	2.12	2.28	2.36	2.63	2.50	3.07	2.48

pumping costs if the Omega Pipe Line Company installed 12-in. pipe and used two pumping stations on the 126-mile line.

Since the working pressures for a 12-in. line are only about 45 per cent of the working pressures of a 10-in. line for given capacities, the kilowatthours per barrel per 100 miles required to pump oil through a 10-in. line using plunger pumps, as shown in Fig. 4, can be converted to kilowatthours per barrel per 100 miles required to pump the same type of crude oil through a 12-in. line and 2 pumping stations, by multiplying the values shown in Fig. 4 by 0.45.

The elevations of stations W, X, Y, and Z of the Omega line indicate that (1) the pumping stations in the 12-in. line could be located at W and Y, (2) that a balanced pressure at each of the proposed pumping stations could be obtained, (3) that the maximum capacity of 40,000 bbl of crude oil with a viscosity of 100 S. sec U. and an A.P.I. gravity of 30 deg could be delivered each day, and (4) that the initial pressures at stations W and Y would not exceed 700 lb per sq in., the maximum allowable working pressure for 12-in. pipe. The comparative costs per year for pumping in the Omega line, for 10-in. and 12-in. pipe, are given in Table 4. The average capacities shown in Fig. 2 were used in making this comparison.

The values in Table 4 indicate that in every year of the operation of the Omega line, the 12-in. pipe line with 2 pumping stations would have operated cheaper than the 10-in. line equipped with four stations. The investment difference is only $30,000 in favor of the smaller line, but this amount is recoverable in operating-cost savings during the first four months of 1929 if the 12-in. line were used.

Again, the results given in Table 4, showing the actual pumping costs for 10-in. pipe through four stations, and 12-in. pipe through two stations, indicate that the larger pipe and a smaller number of stations should be installed. Fig. 7 shows the relation between the velocity of the oil flowing in the 10-in. and 12-in. pipe lines, and the total cost in cents per barrel per 100 miles for both pipe diameters. Note that the lowest operating costs are achieved when the velocity is about 2.5 fps for the average capacity of about 30,000 bbl per day, the actual volume during 1933 and 1935. The fact that lower average pumping charges are achieved with larger pipe and a smaller number of pump stations may lead to the conclusion that the most economical velocity at which to pump oil through pipe lines is somewhere between 2.5 and 3.5 fps.

Conclusion

The mechanical efficiency of plunger pumps is very high and is of the order of 96 to 98 per cent when operated against high pressures.

Again, after analyzing all information and results obtained in this paper, it may be said that plunger pumps driven with electric motors should be installed in trunk-pipe-line stations, if the line is to remain in service 15 to 20 years or longer, and if electric power can be purchased at approximately 1 cent per kwhr for monthly load factors of 75 to 90 per cent. On the other hand, if the proposed pipe line is contemplated to be in use from 5 to 10 years only, and electric power can be purchased for 1 cent per kwhr for monthly load factors of 75 to 90 per cent, the use of centrifugal pumps running at approximately 3600 rpm is economically justified.

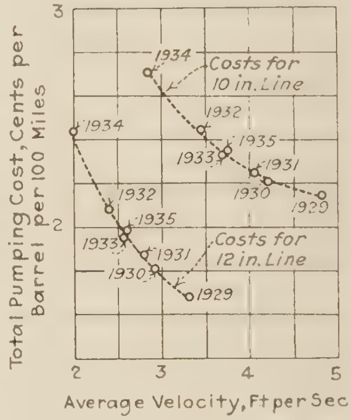

Fig. 7 Comparative Costs for Pumping Oil Through 10-In. and 12-In. Omega Lines

Oil engines to drive plunger pumps should be installed on proposed pipe lines which will have an economic life of 20 years or longer, if cost of crude oil for fuel is estimated not to exceed $1.50 per bbl, and if electric energy is not available or cannot be purchased at high monthly load factors for less than 1 cent per kwhr, and further, if a capacity factor of 90 to 100 per cent can be guaranteed year after year during the entire life, or greater portion of the life of the pipe line.

The history of the Alpha line is that its average capacity factor over 5 years is 77.2 per cent, and the capacity factor of the Omega line is 80.1 per cent over a 7-year period, and yet they are both considered as trunk pipe lines.

Economic use of electric-power facilities on long pipe lines having a number of pumping stations, equipped with either plunger or centrifugal pumps, will now permit definite predictions to be made as to the amount of electric energy required to perform pumping operations when the capacity factor is known, or estimated, by simply raising such capacity factor, expressed as a percentage, to the 2.2 power, to determine the daily, monthly, or annual percentage of the maximum electric-energy requirements for that given period. It is significant that Fig. 6 shows a rapid falling off of total electric-energy requirements when the capacity factor is slightly lowered.

The use of larger pipe diameters and a smaller number of pump stations is fully justified, from a standpoint of receiving a quick retirement of the increased investment of such larger pipe. As a general rule it may be stated that the most economical plan in pipe-line design is to limit the velocity to approximately 3 fps, rather than to use higher velocities of the order of 4 to 5 fps.

Selection of Wood for Industrial Uses

By R. P. A. JOHNSON,[1] MADISON, WIS.

The author discusses the selection of woods for various industrial uses as based upon the physical properties of the woods and requirements which the wood product must meet. He classifies a number of woods according to their warping, end-splitting, turning, planing, and bending qualities, and also rates them in the order of their tendency to transmit odor and taste. Charts are presented which show the distribution of the quantity of wood used in the manufacture of such products as furniture, agricultural implements, automobiles, railroad cars, refrigerators, cabinets, handles, and ladders. The adoption of a wood for the manufacture of a given product and the substitution of one wood for another, based on controlling the physical properties of the wood by treating it, are also discussed.

WISE SELECTION of wood for a given use necessitates first, the determination of the requirements of that use. Good engineering judgment and careful observation are essential to determine which properties are required for satisfactory service and which properties are the most important. The selection of the proper wood is primarily the responsibility of the engineer on the job, because the requirements of use vary with conditions in the plant, the quality of articles produced, and the conditions to which the articles will be subjected in service. The wood best adapted to a given use will, therefore, not always be the same. Ash and southern yellow pine furnish an example of widely different woods used successfully for the same article. Ash is used for bats for college, semiprofessional, and professional ball players. Southern yellow pine serves equally well as ash for bats for small boys of the grade-school age because for children's bats the strength and toughness requirements are not so high. The necessity for careful observation is illustrated in a mistake commonly made in selecting wood for diving boards. Decay-resistant woods are often selected because of the wetting to which the boards are subjected. Diving boards, however, usually fail mechanically in less than two years if they are subjected to continuous use, such as at popular public beaches. The selection of a comparatively high-priced, weak wood of high decay resistance in preference to a low-priced strong wood of moderate or low decay resistance, as is often done, is obviously wasteful, because the purchaser is paying for decay resistance, a property of little or no importance to the use requirement.

[1] Senior Engineer, Section of Industrial Investigations, Forest Products Laboratory. Mr. Johnson received his B.S. degree in civil engineering from Virginia Polytechnic Institute in 1908. He received his M.S. degree in 1928, and a professional degree in civil engineering from the University of Wisconsin in 1931. Since graduation in 1908 he has served continuously in the U. S. Forest Service with ten years service as a forest ranger, land examiner, surveyor-draftsman, and chief of party. For 18 years he has been located at the Forest Products Laboratory conducting researches on the strength of wood, properties and uses of wood, and the selection of wood for farm, home, and industrial uses.

Contributed by the Wood Industries Division and presented at a meeting of The American Society of Mechanical Engineers, held at Niagara Falls, N. Y., September 17 to 19, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until June 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

After the requirements of use are determined, the next step in the proper selection of wood is the determination of a wood with properties which best meet the requirements. Again, good engineering judgment is needed, since it is only in exceptional uses that one wood will excel all others in the properties desired. For example, two important requirements for ladder stock are strength for safety, and light weight for ease in handling. Spruce is light in weight but low in strength when compared with Douglas fir. For each particular type of ladder, it is necessary to determine the importance of the lightweight requirement. Furthermore, the wood best adapted to a use may be higher in price than one which does not meet the requirements so well. The question then is, how much more is the better wood worth? To evaluate the difference in properties, especially when they improve but do not increase the service life, calls for good judgment.

Investigations of the Forest Products Laboratory have resulted in the publication of much information on the properties of wood. This information furnishes a basis for the selection of the wood best adapted to a given use. A large number of the publications contain detailed data on such properties as strength, weight, decay, and painting characteristics. Recently there was published the Wood Handbook,[2] which gives under one cover the accumulation of information previously scattered through a number of bulletins. It contains information on strength, shrinkage, specific gravity, thermal conductivity, electrical resistance, and other properties in units and terms with which the engineer is familiar and knows how to use. No detailed discussion of these properties is possible or necessary in this paper.

Machining and Behavior Properties of Wood

Properties which are not so readily expressed in engineering terms often determine the selection of wood for industrial use. Little has been published on these properties, and it is only through the initiative of the present Wood Industries Division of the A.S.M.E. that any attempt has been made to measure and record them. The absence of engineering data on such properties has resulted in wide differences of opinion as to the extent to which individual species possess or do not possess merit for some particular use. Prejudice and misconceptions regarding such properties have been the cause of considerable loss and poor practice in the use of wood. Recently the Forest Products Laboratory has begun to attack the problem of measuring and recording these properties. The work is still in progress and new methods of measuring, as well as units for recording, have been and must continue to be developed. As a result of the work to date there are now available data which make possible a comparison of a number of hardwood species important in industrial use. The importance of these properties in the selection of wood for some of the industrial uses warrants a brief presentation of the more important properties so far studied.

Warping. Warping is responsible for much waste in fabricating and for some unsatisfactory service. It is defined as: "Any variation from a true or plane surface. Warp includes bow, crook, cup, and twist or any combination thereof." The twist, cup, and bow of samples of southern and Appalachian hardwoods representative of the commercial run of the material were measured and the data combined into the index values shown in Fig. 1.

The results not only make possible a numerical comparison of species but also show that cross grain is the principal cause of warping, and woods with interlocking grain have the highest index.

Splitting in Nailing. The splitting of wood in nailing adversely affects the strength of joints. Splitting is controllable within limits by the shape of the point and the size of the nails. Additional nails will generally increase the strength of the joint. The splitting tendencies of species are, however, important factors in the selecting of wood for certain uses, notably frames to which upholstery is fastened in furniture and automobiles. Tests using seven-penny box nails in $^3/_8$-in. material and varying distances from the ends resulted in the development of the index values shown in Fig. 2. They are based on the number of complete or through splits. While the index figure may change materially under different test conditions, only minor changes in the relative position of species are to be expected under different test conditions. The application of these results should aid materially in reducing losses resulting from erroneous opinions based on casual observations.

Splitting in Screwing. The splitting of wood by screws adversely affects the strength of joints and fastenings. It is an important consideration in determining the size of lead holes in framing on which heavy doors are to be hung or where hardware is fastened to wood. Some woods which split readily with nails make a much better showing with screws.

The classification of the species in Fig. 3 is based on the complete splits resulting from tests made under severe conditions, namely, with screws of several sizes driven into $^3/_8$-in. stock near the end. The property is important in the manufacture of refrigerators, automobile body frames, boats, and agricultural implements.

Turning. There is considerable difference in the character of surface obtained in turning different woods. The importance of turning qualities in the selection of wood lies in the amount of sanding required to make turnings acceptable and the number of culls. In the past turning qualities have been described only in general terms. The numerical values shown in Fig. 4 were obtained with a modified back knife using specimens conditioned to 6, 12, and 20 per cent moisture content. The results showed that some species, such as beech and pecan, turned well at any moisture content whereas other species, such as willow and cottonwood, give good turnings only at about 6 per cent moisture content. The difference in species can be reduced by drying to a proper moisture content. The property is important in the selection of wood for furniture and interior trim.

Planing. Much better technic is required with some woods than with others to obtain smooth surfaces with a planer. Species differences can be largely eliminated by proper control of speed, moisture content, and cutting angle. High cutter-head speeds (5400 rpm and 54 fpm feed) gave better results than low speeds (3600 rpm and 36 fpm feed). The numerical classifica-

tion shown in Fig. 5 is based on the chip marks, chipped, raised, and fuzzy grain that developed in planing samples at 6, 12, and 20 per cent moisture content with a cabinet planer having knives set at a 30-deg angle and operated at the two speeds just mentioned. It is possible that additional work using different knife angles will show how to reduce further differences due to species. Good planing qualities are desired in practically all industrial uses of wood.

Odor and Taste. A tendency to impart odor or taste bars some woods from a number of industrial uses. The classification shown in Fig. 6 is based on ash as 100 and is the result of tests in which butter was used as a test medium. Butter was used because of its susceptibility to contamination. Woods unsuited for use in butter containers can often be used safely when food does not come in direct contact with the wood such as in refrigerators. Any of the first six woods listed in Fig. 6 can be used satisfactorily for butter containers. Service tests are required to determine the line between acceptable and unacceptable woods for other uses, but any wood acceptable for butter containers can be used safely for other purposes where a tendency to impart odor or taste is objectionable.

Bending. Most hardwoods can be bent readily into a curved form. The comparatively low toughness of softwoods as a group makes them difficult to bend without excessive breakage. The bending index figures shown in Fig. 7 are based on tests of specimens selected at random with only knotty, decayed, and checked pieces excluded. Many of the specimens would not be considered suitable for bending stock because of cross grain they contain. The index shown in Fig. 7 is a measure of the care necessary in selecting and handling the different woods rather than a measure of the waste that would result from their use, because the specimens were bent without end pressure or support on the outside of the bend. Bending operations on carefully selected material, with equipment capable of supplying the proper end pressure and back support, would in all probability result in a much smaller spread between species. The index shown in Fig. 7 is an aid in selecting woods suitable for boat building, certain types of furniture, and other uses.

Use of Data on Machining and Behavior Properties. The numerical values shown in Figs. 1 to 7, inclusive, should not be used for computing waste because limitations are placed on them by test conditions and method of selection. They will in all probability not hold under conditions differing materially from those under which the tests were made. The relative position of species, however, should remain about as shown. The charts should prove a valuable aid until better values resulting from continued work are available in comparing species, and in evaluating properties previously arrived at by guess or superficial observation.

Woods Used by Selected Industries

An important aid in the selection of wood for a given use is a knowledge of woods which are and have been used for the purpose. The woods used indicate fairly well the requirements of the use. When maple, for example, is the principal wood used it indicates that strength and uniform texture are more important than decay resistance and ease of working.

There are available data on the woods used by 48 principal wood-consuming industries. These data, given later in this paper, were collected by Forest Survey of the U. S. Forest Service in cooperation with the Bureau of Census for the years 1928 and 1933. Additional data collected by the states between 1909 and 1913 show the woods used in that period. Ten industries have been selected with the aid of the Wood Industries Division of A.S.M.E. to illustrate the character of data available. The decreased consumption shown in 1933 is largely due to economic conditions. In some uses there has also been a loss of the market for wood.

Furniture. The distribution of woods used in manufacturing furniture is shown in Fig. 8. These woods may be roughly divided into two groups: (1) Woods used for exposed parts, and (2) woods used for concealed parts.

Appearance, style, and finishing qualities are the properties dominating the selection of woods for the first group. Ability to stay in place, nonsplitting, good holding power for screws and nails are important requirements of the second. Properties and use data are of little value in the selection of wood for exposed parts of furniture. The shifts from one wood to another are practically unpredictable from year to year.

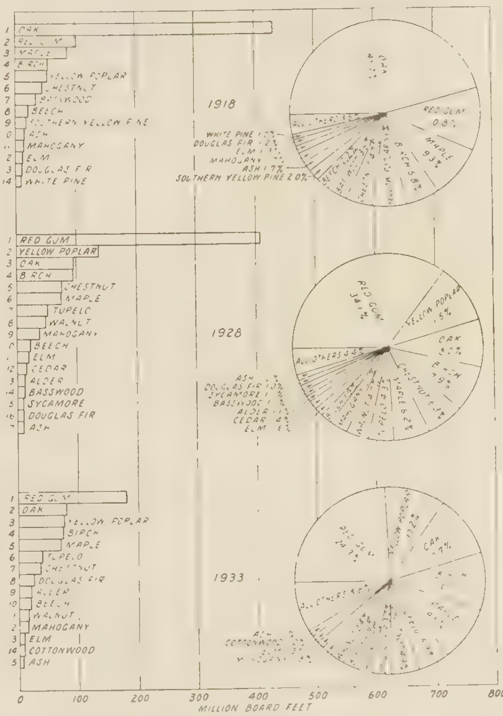

Fig. 8 Distribution of Woods Used in the Manufacture of Furniture

Red gum, yellow poplar, maple, chestnut, and tupelo hold an important place as furniture woods regardless of shifting styles. These woods are used largely for core stock or framing and are selected on the basis of their properties rather than their appearance. Red gum and maple are also used as finish woods.

Motor Vehicles. Strength, uniform working qualities, and high nail- and screw-holding qualities are desired in wood for automobile body frames. Fig. 9 shows oak, red gum, and maple as the principal woods used. Hickory dropped to a minor position with the adoption of wire and disk wheels. The choice between maple, oak, ash, and elm is largely one of availability and cost. The woods are used interchangeably, sometimes all three being used in a single built-up part. Maple is generally preferred because of its uniformity, working qualities, and high strength. Red gum has the advantages of low weight combined with medium strength and nail-holding power. These combined with price and uniform texture are responsible for its use in low-priced cars.

Railroad-Car Construction. The outstanding woods for railroad-car construction and repair are southern yellow pine and Douglas fir as shown in Fig. 10. Availability and price are probably a larger factor in the extensive use of these woods than their

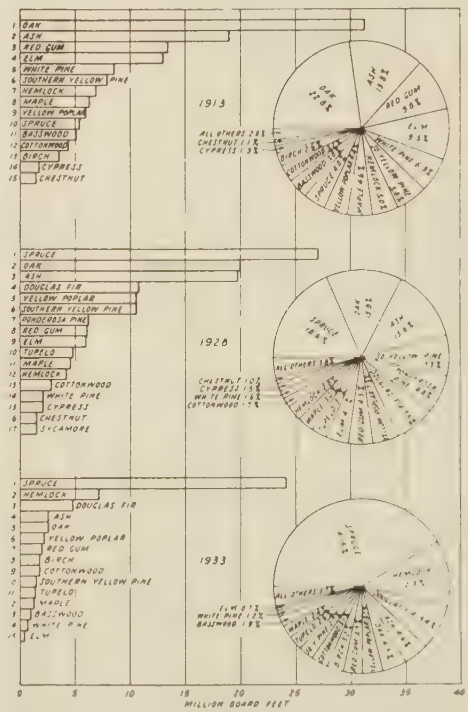

FIG. 12 DISTRIBUTION OF WOODS USED IN THE CONSTRUCTION OF REFRIGERATORS AND KITCHEN CABINETS

strength, decay resistance, and ease of fabrication. Oak is still used in frames for its shock-resisting and high nail- and screw-holding qualities. The substitution of steel for oak is largely responsible for the percentage decrease in its use as shown in Fig. 10.

Agricultural Implements. The requirements for agricultural

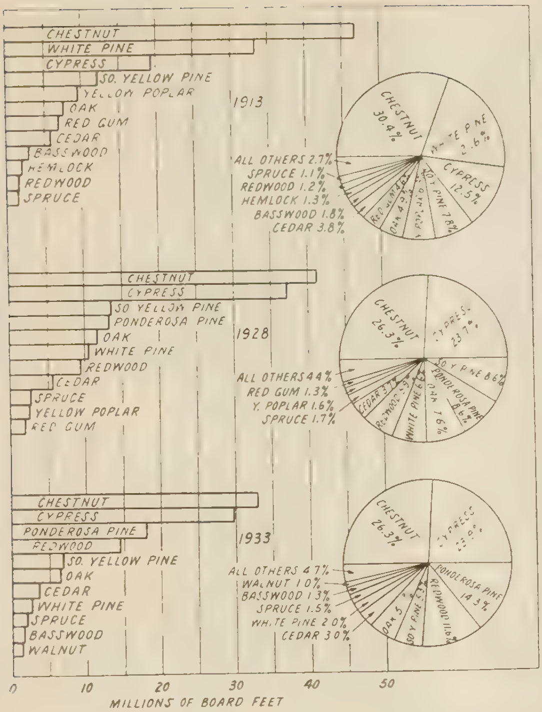

Fig. 13 Distribution of Woods Used for Caskets and Coffins

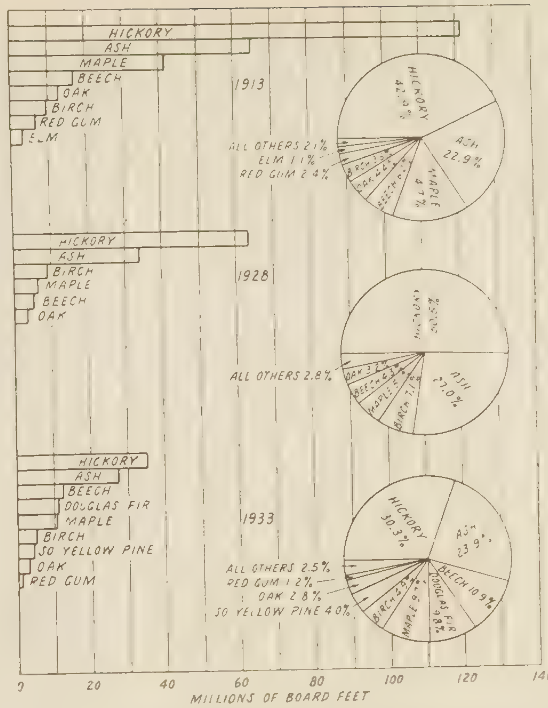

Fig. 15 Distribution of Woods Used for Handles

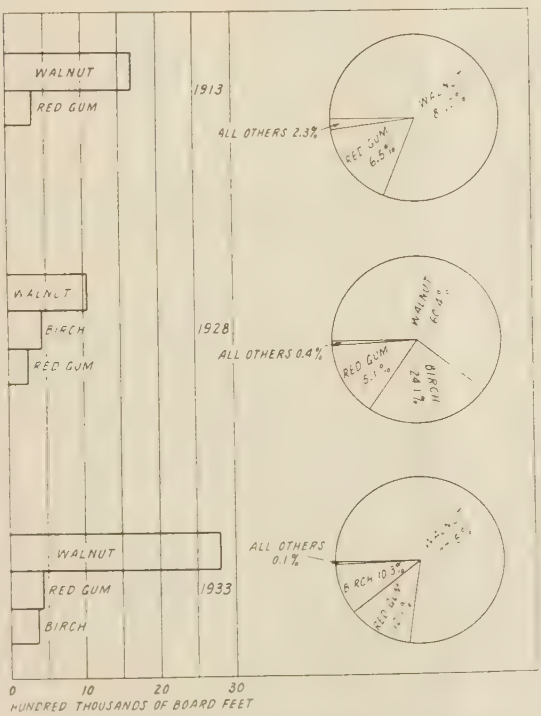

Fig. 14 Distribution of Woods Used in Firearms

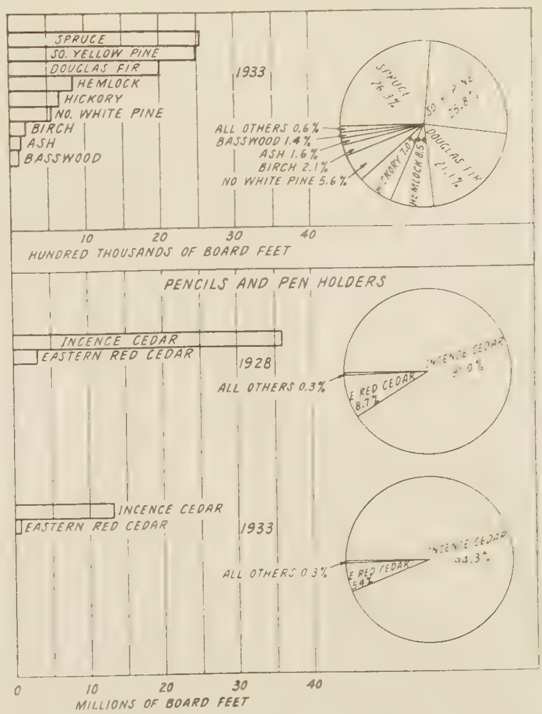

Fig. 16 Distribution of Woods Used for Ladders, Pencils

implements differ with individual units. Hay rakes, threshing machines, and seed drills not only differ widely in their requirements but the requirements of individual partsal so differ. It is difficult to generalize over such a wide range. Fig. 11 shows that southern yellow pine and oak are the woods most extensively used. Oak is used because of its toughness and southern yellow pine because of its ease of seasoning, light weight, moderate strength, and price.

Refrigerators. The wood requirements for refrigerators have been entirely changed by electric refrigeration. The steel cabi-

net has replaced the wood cabinet, which accounts for the reduction in the use of oak, ash, and elm shown in Fig. 12. The predominating woods are now spruce, hemlock, and Douglas fir. These woods are used for frames. The hemlock and spruce differ little in strength. Hemlock is slightly heavier and stronger than spruce but the latter is stronger for its weight. Neither spruce nor hemlock impart any objectionable odor or taste to food. Both woods are low in decay resistance. Douglas fir is stronger and has more decay resistance than spruce or hemlock, but it has a slight resinous odor. The principal woods used are selected because of their availability and price rather than their properties, although woods with a strong odor are banned.

Caskets and Coffins. Decay resistance is considered the most important requirement for caskets and coffins. It is responsible for the extensive use of chestnut and cypress, as shown in Fig. 13. Observations made on caskets and coffins removed from a burial ground after 20 years indicate the failures that had occurred were principally mechanical. Where decay was responsible for failure, it was found that all heart grades had not been used. The mechanical failures do not indicate the necessity of selecting other species, but rather the necessity of improved bracing and design.

The trend toward uncovered hardwood caskets introduces a new requirement. Appearance is important in uncovered wood caskets and will result in an increased use of woods with high or moderate decay resistance, as black walnut, chestnut, white oak.

Firearms. Black walnut, as shown in Fig. 14, is the outstanding wood used in firearms. It meets the requirements for beauty, stability, and hardness. Birch and red gum are used in lower-priced guns. Birch has the hardness but lacks the stability of walnut. Red gum has neither the hardness nor the stability of walnut, but is used as a substitute because it can be finished to closely resemble walnut.

Handles. Hickory and ash stand out from other woods in their ability to meet exacting requirements of handles as shown in Fig. 15. Hickory is outstanding because of its combination of toughness, stiffness, and breaking strength, all of which are required in axe, maul, and similar handles. In addition, hickory turns well and wears smooth. Ash is outstanding because of its high toughness and breaking strength, for its weight, and its low warping, all of which are the requirements for pitch forks, rakes, hoes, and other long handles subjected to heavy use. Beech, birch, and maple are extensively used for hammers, small tools, and other short handles where smoothness in turning is more important than weight or toughness.

Pencils and Pen Holders. The requirements for good pencil wood, as stated by manufacturers, are even texture, straight grain, softness, slight brittleness, dark red in color, slightly aromatic, and light weight. The requirements that wood be dark red in color and slightly aromatic are interesting in that they have nothing to do with the serviceability of a pencil.

Eastern red cedar was and is still considered the outstanding pencil wood of the world. Incense cedar has supplanted eastern red cedar as shown in Fig. 16, not because it is considered better, but because of an inadequate supply of eastern red cedar. Brittleness is also a questionable requirement because the preferred eastern red cedar is more than twice as tough as incense cedar. Eastern red cedar is also the hardest of the cedars, indicating, that within limits, hardness is not so important as it is rated. The search for a substitute for eastern red cedar has been complicated by an erroneous conception of the actual property requirements. Any of the cedars, a number of junipers, redwood, and white pine all have properties favorable to their use as pencil woods. Prejudice prevents their serious consideration.

Ladders. The properties that contribute to satisfactory service have been used to classify woods for use in ladder construction. The classification groups woods for side rails on the bases of the required percentage increase or permissible decrease of requirement for spruce for each cross-sectional dimension.[3]

Spruce is not only the standard but is also the principal wood used in the construction of ladders, as shown in Fig. 16. Its high ratio of strength to weight is largely responsible for its high rating as a ladder wood. Its light color is responsible for the demand for light-colored wood for ladders, although color has no service value and appearance is of minor or no importance in ladders. Western hemlock, which ranks next to spruce in the use of wood for ladders, makes an excellent substitute for spruce. While the properties of western hemlock do not meet ladder requirements as well as spruce, some manufacturers have found it easier to obtain satisfactory hemlock than spruce, principally because the best quality of spruce is selected for airplanes and other more exacting uses. Southern yellow pine and Douglas fir are used in ladders where the strength-weight ratio is not so important. They make stronger but heavier ladders.

Rungs and cleats of ladders are of hard woods, white ash being used as a standard. Fig. 16 shows that hickory is the principal wood used for this purpose. Hickory is superior to ash in strength and wearing qualities. It is, however, heavier and does not have as favorable a strength-weight ratio.

Significance of Species Used. The extensive use of wood for a given purpose indicates that it has been found acceptable by the cut-and-try method. It does not necessarily indicate that it is the best wood for the use. The best wood may be too high priced or the cut-and-try system may not have considered all possible woods, or a wood previously not readily available perhaps now is obtainable.

The selection of wood to replace one that has proved satisfactory is fairly simple. The properties of available woods are compared with those of the wood in use. The selection of the best substitute requires good judgment in evaluating the differences in properties, especially the elimination of the nonessential properties. When a wood in use is not satisfactory, the selection of a wood that will give satisfactory service depends on a knowledge of the exact cause of failure. Strange as it may seem, decay-resistant wood of the same or lower strength is often selected to replace a wood that has failed mechanically. Moreover, woods which are non-decay-resisting are often selected to replace woods that are being replaced because of decay.

The Importance of Species

The general tendency is to overemphasize the importance of species. The importance of small differences in species is magnified, the variability of wood of species is ignored, and there is a tendency to assume that all wood of one species is superior to all wood of another. There is always considerable overlapping in strength and other properties of all competitive species. Well-selected wood of an inferior species is better than poorly selected wood of a superior species.

Design and treatment are great equalizers of species. A well-designed article made of a comparative inferior species will usually give better service than a poorly designed article made of a superior species. Differences in strength can be compensated for by differences in size. Differences in decay resistance can be compensated for by treatment and better protection from moisture. Differences in working qualities can be compensated for by the control of the speed of machinery, angles of knives, and moisture content of stock. Warping and shrinkage tendencies can be partly controlled by selection. With the exception of a few uses with exacting requirements any one of a number of woods can be used if proper design and treatment are applied.

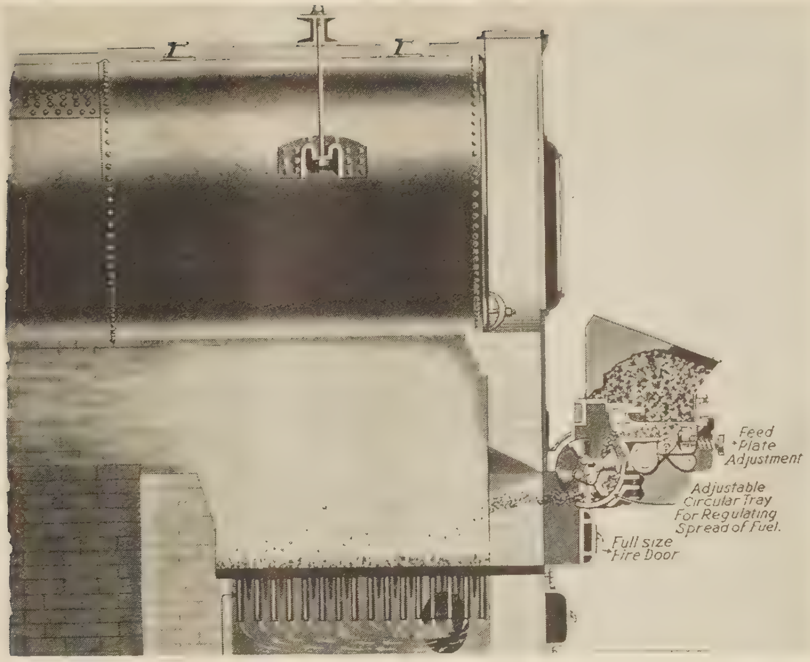

Fig. 1 Underthrow Spreader Stoker With Paddles Revolving So As to Throw the Coal at the Bottom Point of the Revolution

The Forced-Draft Spreader Stoker[1]

By J. F. BARKLEY,[2] WASHINGTON, D. C.

The author discusses the types of spreader stokers in use together with their adaptability for different boiler installations and for burning different grades of fuel. He presents the reasons for their adoption in various Government plants where boilers range in capacity from 100 to 400 hp. The paper contains a table of data showing the results of a number of complete boiler tests conducted on installations equipped with spreader stokers.

THE TERM "forced-draft spreader stoker" as used in this paper covers forced-draft fuel-burning equipment in which the fuel is spread or thrown into a combustion space, part of the fuel burning in suspension somewhat similar to pulverized-fuel applications and part dropping onto a high-resistant type of grate on which the burning is completed. The fuel may be thrown in by revolving paddles or may be blown in with air. Some of the air required for combustion is supplied over the grate, and the remainder comes up through the grate.

The most interesting and effective development period of this type of stoker in this country reaches from, say, 1929, when there were relatively few such applications, up through the last two or three years, during which the rise in the number of sales, relative to other types of stokers, has been remarkably great. Previous to this somewhat arbitrarily chosen period, there were various developments leading toward the spreader stoker. Some of the first attempts to fire coal mechanically included schemes to imitate the fireman's throwing in of coal onto a grate. Revolving paddles turning at very low speeds appeared many years ago. Later, some natural-draft hand-fired bituminous-coal installations were improved by the use of paddles revolving at high speeds. The pinhole type of grate for hand-fired installations using forced draft early came into being for burning fine anthracite. It was when the combination of high-speed paddle and pinhole grate was applied to the burning of bituminous coal by J. A. Hoffman, of the Detroit Edison Company, that combustion events were noted that have led to the present status of the spreader stoker. It was found that there was considerable suspension burning; that the ash particles falling to the grate assumed a fluffy appearance; that the fuel bed on

[2] Supervising Engineer, Fuel Economy Service, U. S. Bureau of Mines. Mem. A.S.M.E. Mr. Barkley holds the degrees of B.S. and E.M. from the Michigan College of Mines. In 1911 he served as an instructor in the New Mexico School of Mines and for the next two years was associated with the Westinghouse Electric & Manufacturing Co. After four years with the Bureau of Mines he took the position of special engineer with the Carnegie Steel Co., where he remained until 1923. In his present capacity he serves as consultant on design, operation, and fuel use in federal fuel-burning plants. He is a member also of the A.I.M.E. and has contributed articles to Bureau of Mines publications and technical magazines in the fuel field.

Contributed by the Fuels Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the grate could be kept surprisingly level, the dancing of the fuel particles thereon aiding the spreading effects of the paddles; that a thin bed of burning fuel could be maintained on the grate, beneath which was a bed of ash that gradually increased in thickness; that the ash was kept relatively cool due to the high proportion of air coming up through the grate, the high temperatures of burning being well above it; that the carbon in the refuse could be quickly burned out to very low amounts by stopping the coal feed; that good CO_2 could be obtained, the equipment being quite sensitive to adjustment; that quick responses to load changes could be had; that a wide range of coals could be used, the caking characteristics being of no particular moment and the ash fusion little more; that the maintenance of the grate and spreader equipment, both being out of the fire, was practically negligible; and that the operation was simple and readily understood by the ordinary small-job fireman. Such inherent characteristics and advantages warranted development studies; it might be noted at this point that inherent freedom from smoke and fly-ash emission is not listed. Fig. 1 might be considered representative of the beginning stages of the development. As installed under the horizontal-return-tubular boiler, ample space for flame length and combustion was provided; the combustibles and overfire air supplied near the coal feed passed at right angles over the grate from which the air and gases rose vertically; ratings were relatively low, and most of the fly ash fell into the back chamber where its carbon content slowly burned out. A simple on-and-off control based on the steam pressure was used, a setting being made on the spreader for a chosen rate of coal feed and on the forced-draft air inlet for a chosen rate of air. Two sets of revolving paddles were desirable. The fire was cleaned one side at a time; the coal feed to one set of paddles was cut off for a few minutes, during which time the carbon in the ash on that side of the grate was burned out. This ash was pulled out the upper door with a few pulls of a hoe, usually onto the boiler-room floor. If for any reason the paddles could not be operated, hand-firing could be done through the upper doors.

The modest beginnings of the establishment of the stoker's place in the fuel-burning industry might be illustrated by experiences of the federal government as purchaser and user. The government operates a great number of small plants located over the entire United States, having boilers from about 100 hp up to, say, 400 hp. Many different coals must be used; a considerable number of these plants are rather isolated, some being many miles from a railroad. Trouble was experienced in the plants due to equipment maintenance, continual replacements of parts, fireman inabilities, prejudices and complaints, ash and clinker troubles, low efficiencies, and difficulties in choosing coal. Frequently, solutions of individual cases resulted in buying some particular and expensive coal. The spreader stoker came to the attention of the federal government. With perhaps some justifiable misgivings, a study was made of it and installations were inspected. It was quite apparent that the use of this stoker would be an improvement, relieve many plant troubles and not merely replace them with some other kind of troubles. An installation was made under a 200-hp cross-drum water-tube boiler at an Indian reservation near Mt. Pleasant, Mich. It was an immediate success. Young, inexperienced Indian boys served as firemen. The coal used was the cheapest west Kentucky slack having an ash content of about 15 per cent and an ash fusion of approximately 2000 F. The equipment operated satisfactorily; it was easy to carry the plant load continually, maintenance costs practically disappeared, and total costs were low. Based on these experiences the government began installing these stokers in chosen places all over the United States, burning coals from anthracite rice to lignite slack. They were ideally suited, for example, to the federal penitentiaries. Convict firemen could easily operate them; any temptation to "accidentally" cause the breakage of a part that would stop the stoker was put out of mind by the thought that it would then be necessary to fire by hand through the upper doors.

The continued installing of such an unorthodox stoker brought up many questions, particularly to and from competitors of other types of equipment. What actual efficiencies could be shown by tests? What CO_2 could be maintained without CO? What about fly ash and smoke? All of these questions were interesting and were to be answered as developments permitted. Using again the government as an example, it was quite apparent at the time that such technical considerations could have only slight effect on the general result for the cases at hand. Troubles were being eliminated and money saved. It was not what could be shown by tests but what actually happened at a plant over a period of time.

As the use of the spreader stoker broadened, new problems of application brought new developments and refinements. These exact details varied with the several manufacturers entering the field. Engineers were slow to realize the importance of the type of grate, especially for the more exacting requirements. A high-resistant grate meant practically a uniform air flow throughout the grate area, regardless of any temporary irregularities in the resistance or thickness of the fuel bed, and better cooling effect was obtained; the higher velocity air also gave better dancing of the particles. Air zoning came into use; that is, an air zone for each spreader, making in effect two or more stokers per boiler. It has been found that preheated air can be successfully applied to this type of stoker. Grate areas were usually made liberal for most small boilers, extending across the width and from about 6 to 8 ft deep for cases where the ash was pulled out by hand. Where the loads were unexpectedly low, it was occasionally found advantageous to brick off some of the grate area. For the larger boilers, questions arose regarding the pounds of coal per square foot of grate area and depth of spreading capacity of the spreader. Tests are recorded of the burning of as high as 100 lb of coal per sq ft of grate area per hr. A depth of spread of about 12 ft has been used. Dumping grates appeared, both hand- and power-operated. Ash could be quickly and easily dumped into hoppers beneath the boiler-room floor. This was of particular advantage for the deeper grates and larger boiler installations. Where the ash must be hoed onto the boiler-room floor for disposal, it seldom is of advantage first to dump it into the plenum chamber, to be hoed out later. With the higher burning rates and temperatures, some clinkering difficulties began to appear, especially with the higher-ash coals of low ash-fusion temperatures. If the ash bed was allowed to build up too thick or remain on the grate too long some clinkering might occur. More frequent dumping solved many such cases. An air-cooled carborundum brick along the grate line was used for other cases. Larger boiler installations, running at high ratings are now equipped with water-cooled furnaces.

Since the spreader stoker is an overfeed stoker, the engineering problem of preventing smoke production was early encountered. From the standpoint of smoke emission, the spreader stoker operates something like an oil burner—it is very sensitive to the human element. A slight turn of the hand, giving too much fuel feed for the air, immediately gives excessive smoke. Vertically baffled boilers usually do not provide the length of flame travel or the same kind of mixing provided by the long, horizontal combustion chamber of horizontal-return-tubular boilers. The high load-carrying capacity of the stoker tempted firemen to carry higher loads and use fewer boilers than planned. This

led to studies of proper furnace designs and sizes together with heat releases, admission of overfire air, and use of steam jets. Where the prevention of smoke is an important feature for a given installation, matured, extremely conservative, and not merely optimistic engineering decisions must obtain. Anthracite and semianthracite coals will give no trouble from smoke, but all bituminous and lower-rank coals may do so. For these coals, the author prefers space for a flame travel of at least 14 ft, and such flame travel to be horizontally across the grate if possible.

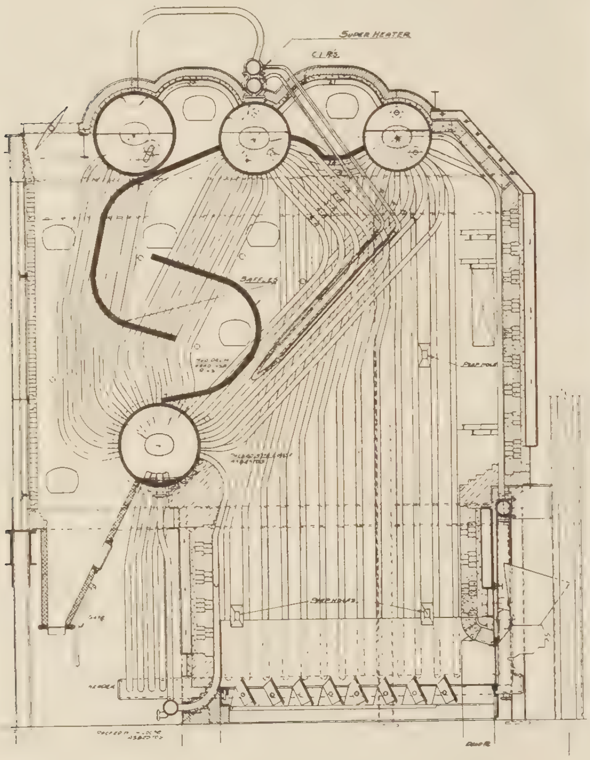

Fig. 2 Underthrow Spreader Stoker With Dumping Grate on a 1000-Hp Four-Drum Bent-Tube Boiler—the Grate Depth Is Approximately 11 Ft. The Ash-Hopper Arrangement Is Not Shown

Heat releases from about 20,000 to 35,000 Btu per hr per cu ft of furnace volume usually are used. On one test, a heat release of over 100,000 Btu was obtained but made much smoke. Furnace temperatures not over 2400 F ordinarily are desirable. The amount of water cooling to be used on the larger installations can be figured much the same as for other types of fuel-burning equipment, taking into consideration the CO_2 to be carried and the fusion temperature of the ash. The temperature of the furnace has a bearing on the possibilities of the slagging of the boiler tubes. Much study has been given to the admission of overfire air. It may serve for metal-cooling purposes, and aid coal distribution as well as combustion. Where furnace conditions are poor, considerable improvement in smoke emission may be obtained by the use of steam jets or air jets properly set in the furnace. A cross fire from jets at the front corners of the setting, aimed somewhat downward toward the rear of the grate, is quite effective in decreasing smoke. Some test results of steam jets are given in Table 1. Proper engineering is bringing forth better types of installations that are meeting smoke ordinances, as well as other types of fuel-burning equipment using bituminous coal or oil.

Fly-ash problems also came to the front with this stoker. Throwing fine coal up into space to be burned gives fine ash particles a good start on a flight with the products of combustion. With vertical baffles, fly ash that with horizontal baffles would have dropped behind the bridge wall went on into the boiler passes. The amount of fly ash depends not only on the load, and the total amount of ash, but also on the type of coal. Although anthracite and semibituminous coals give more ash carry-over than some of the lower-rank coals having some 10

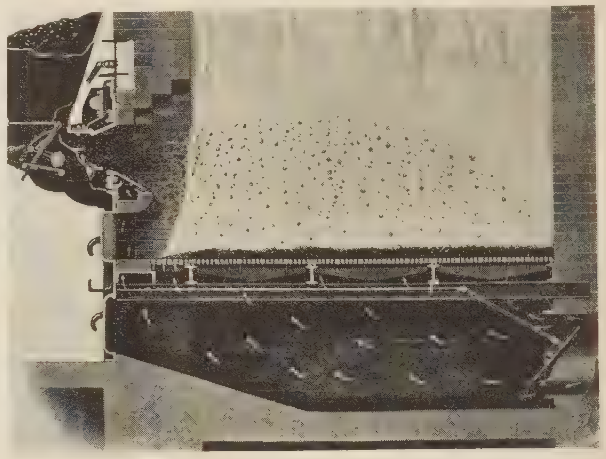

Fig. 3 Overthrow Spreader Stoker With Paddles Revolving So As to Throw the Coal at the Top Point of the Revolution

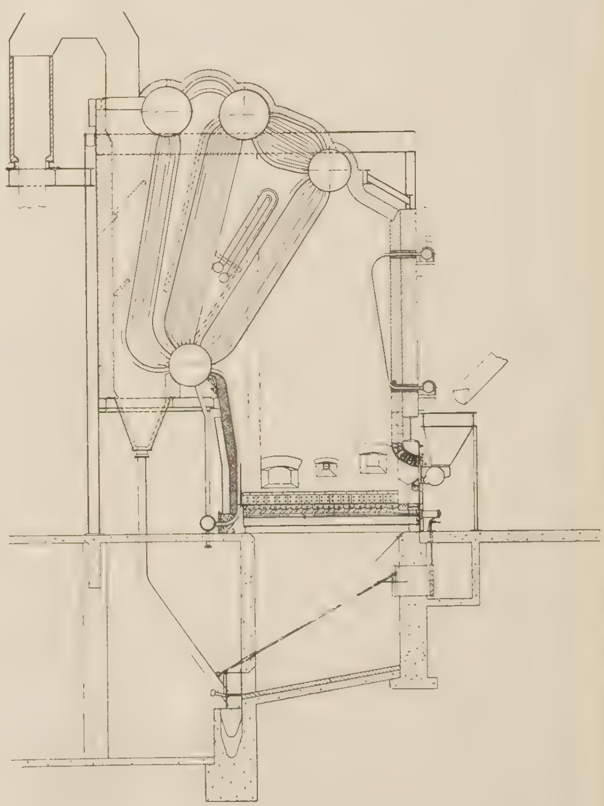

Fig. 4 Overthrow Spreader Stoker With Dumping Grate on a 1000-Hp Four-Drum Bent-Tube Boiler—the Grate Depth Is Approximately 11 Ft

per cent inherent moisture, it cannot always be judged exactly what relative carry-over may be expected for some particular coal. Where there is excessive fly ash, collecting-hopper arrangements may be provided in back chambers and passes in the boiler; some well-designed installations provide an ejector that returns the fly ash from a boiler pass back to the combustion chamber. This arrangement helps burn out any carbon content. Simple forms of baffle-type cinder catchers may be installed in breechings. It is necessary to dump these hopper arrangements regularly. Fly ash should not be permitted to accumulate too much in any one spot, such as along the bottom of the breeching, because it may suddenly lift all at once and go out the stack, creating considerable nuisance. Cinder-catching types of induced-draft fans are applicable. Some fly ash will also usually accumulate at the base of the stack. Keeping all passages clean is a great help in eliminating the fly-ash nuisance. One fireman remarked he would rather take loose sand-like fly ash from behind the bridge wall than fight with clinkered ash in front of the bridge wall. The combustible content of the fly ash may be practically zero for cases where it may subsequently burn out, as in the back chamber of a horizontal-return-tubular boiler; at the other extreme, it has been found as high as 85 per cent for cases where there was little aftercombustion, as at the bottom of the second pass of a vertically baffled boiler. More real attention is now being paid to fly-ash emission from all types of forced-draft fuel-burning equipment. Many of the recently designed government plants are using baffle-type cinder catchers. Some test measurements of fly-ash amounts and combustible content are given in Table 1.

In carrying out the general principles of this stoker, various methods have appeared for throwing or spreading the coal. These methods may best be described by referring to Figs. 2 and 8. Fig. 2 shows an installation of a paddle-type underthrow spreader stoker in which the paddles revolve so as to throw the coal into the furnace at the bottom point of the revolution. The underthrow-type stoker is shown in more detail in Fig. 1. Figs. 3 and 4 give similar views of a paddle-type overthrow spreader stoker in which the paddles revolve so as to throw the coal into the furnace at the top point of the revolution. Fig. 5 shows an installation of a spreader stoker in which the spreading is done with an air jet, the coal being conveyed by air from some convenient location point of the coal hopper and fan. Fig. 6 shows a method of spreading the coal with steam-air jets, the coal being brought from the hopper to the jet with an adjustable screw feed. Mention at this point might also be made of a jet type of coal throw used on locomotive stokers. Development work has been done in adapting this particular type of jet for stationary work, using either air or steam. Figs. 7 and 8, from *Steam Engineer*, London, show a form of application developed in Germany at the Stinnes collieries in the Essen district. This development resulted from a desire to eliminate the grinding of coal in pulverized-fuel-burning systems. It is interesting to note the following quotation, in regard to this system, taken from the *Steam Engineer:*[3]

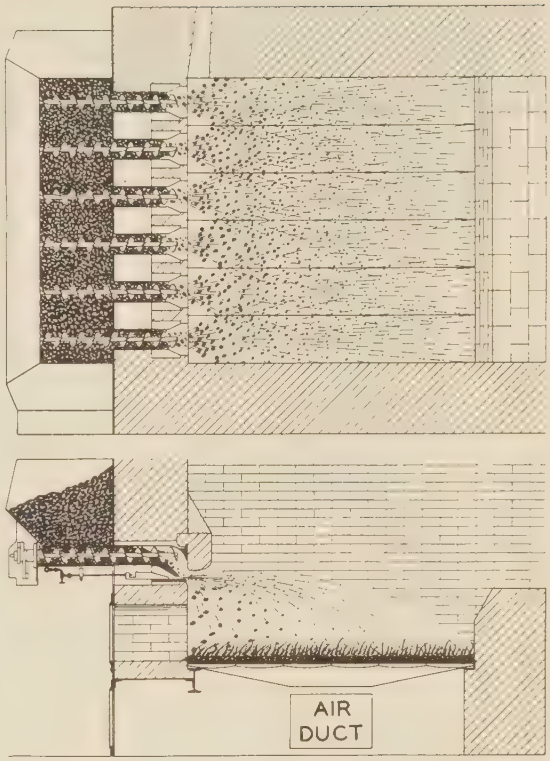

Fig. 6 Spreader Stoker in Which the Coal Is Spread by Steam-Air Jets

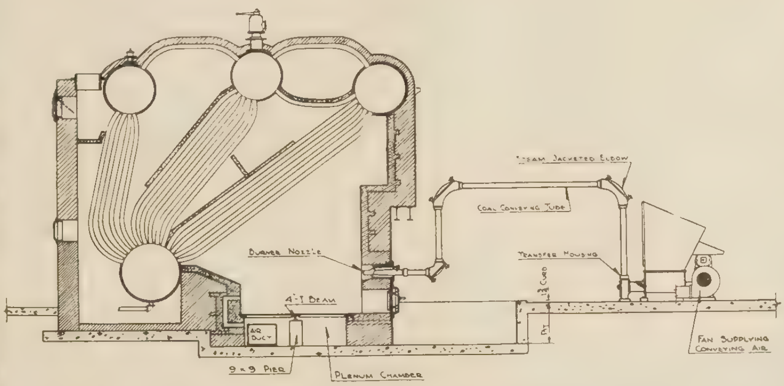

Fig. 5 Spreader Stoker in Which the Coal Is Spread by an Air Jet

"The smaller and lighter grades of fuel are consumed in suspension, and the heavier particles which have been partly burned in the combustion zone descend to the bottom of the furnace, which is composed of slabs of refractory material in which air channels and orifice jets are provided . . . . . Owing to the granulating effect of the secondary air from the jets the ash can be readily blown out or raked out . . . . Doubtless operating engineers will be interested to know that the ash residue in this type of furnace does not give any trouble, having regard to the great difficulties which have had to be overcome in developing the orthodox pulverised-fuel fired furnaces to assure ease of ash handling with maximum efficiency of combustion."

The early type of on-and-off control, although still desirable for some installations, in general soon gave way to continuous types of control. The stoker, with its small amount of fuel on the grate, was found to be quite sensitive to changes of adjustments. It was a relatively simple problem to carry out principles of control which had reached a high state of development on other types of fuel-burning equipment. As before mentioned,

[3] "Dust Coal Burned in Suspension Without Pulverizing," *Steam Engineer*, vol. 1, August, 1932, p. 474.

in the spreader stoker the thickness of ash on the grate continually increases from cleaning to cleaning. Control devices have appeared for the purpose of compensating for the slight increase in draft loss resulting therefrom. One type uses what might be described as an auxiliary or secondary control that maintains a constant volume of air from the fan through the fuel bed for every main fuel-air setting. This secondary control may be actuated by the drop in pressure across an orifice in the main air duct or by any differential pressure that varies with the total air flow. In this type, the boiler damper operates directly from the pressure in the combustion chamber and is independent of the remaining controls. Another simpler type for this purpose eliminates the auxiliary control by means of the old familiar method of operating the boiler damper direct from the steam-line pressure, the forced-draft fan operating from the pressure in the combustion chamber. With any of these controls, some hand adjustment may be necessary when the size of the coal changes appreciably during operation. On the paddle-type stokers it is also quite customary to provide hand control for the speed of the paddles, which affects the spreading.

Fig. 7 German Spreader Stoker in Which the Coal Is Blown Into the Furnace by Air

It is frequently desirable to have a smoke indicator of some type so that the operator may know what is being emitted from the stack or from each boiler. This may be a simple mirror, or periscope, or one of the more highly developed indicators. One type can be set to show when a chosen "haze" in products of combustion is maintained; when the gases become too lean with excess air, a bulb of one color is lighted; when there is a lack of air, a bulb of another color is lighted. This serves very well as a combustion indicator. Some types ring a bell or blow a horn when the smoke reaches a chosen maximum.

As a general statement, the spreader stoker will show on test about the same overall boiler efficiency as an underfeed stoker, with the exception of the carbon loss in the fly ash. On installations that provide for the burning out of this carbon, such difference would practically disappear. The author recalls watching one installation that was automatically controlled by the two-pen system and arranged to return the fly ash periodically into the combustion chamber. At the time the fly ash was returned, the coal feed cut down. The foregoing comparison of test efficiencies is made where a coal is being burned that the underfeed can readily handle. On the poorer coals, the spreader stoker is at a distinct advantage. Under regular operating conditions, it has been found on our installations that in general the firemen will more nearly approach test efficiencies with the spreader stoker than with the underfeed stoker.

The data in Table 1 giving the results of tests of paddle-type

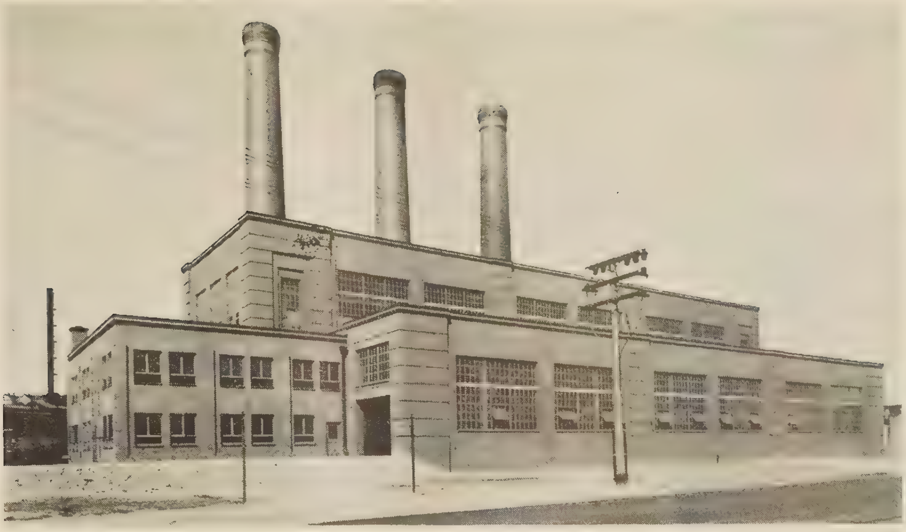
Fig. 8 German Spreader Stoker Installed on a 750-Hp Water-Tube Boiler

stokers were chosen largely from the standpoint of the use of different coals. Considerable test data have accumulated by this time, the government having at present about 50 plants equipped with spreader stokers. These tests, with the exception of those marked Veteran's Administration, were run by L. R. Burdick, a member of the A.S.M.E., and the author. Like all such data, the tests are quite individualistic and do not necessarily show the best or the worst that the stoker might do under different conditions, but indicate what happened under a given set of conditions. Tests 1 and 2 give data on the use of anthracite buckwheat. At one government plant, this fuel is giving the lowest total operating costs, even with rather low boiler efficiency. Somewhat better results are obtained with anthracite buckwheat by feeding intermittently instead of continuously. This approaches the ordinary way of hand-firing such fuel. Some hand work on the fuel bed is needed occasionally. The liveliness of the burning of the anthracite, somewhat expressed by the volatile content, has a decided effect on its use in this stoker. In test 2 better stoker action from the general combustion standpoint was obtained with an 8 per cent volatile anthracite than with the 5 per cent volatile anthracite used in test 1. Less handwork was necessary. Test 4 shows the same boiler and stoker when a 22.7 per cent volatile bituminous coal was used. Test 5 shows the use of a high-ash semianthracite which is being used continuously at one government plant. The stoker action is good, but, due to the high ash, the cleaning periods must be quite frequent. Tests, 6, 7, 8, 9, and 10 show the use of higher volatile bituminous coals. Approximate smoke-reading averages are included for tests 6, 7, 8, and 9. Tests 7, 8, and 9 have high heat releases. The boiler setting was too low on this installation. Tests 11 and 12 show the use of sub-bituminous coal, and test 13 shows the use of lignite. Both of the plants at which the tests were made are using these fuels continuously.

There are also added some specific data in Table 1 on the effect of cross-fire steam jets on the CO_2 obtainable, smoke emission, and approximate heat releases. These data were taken on a boiler set too low, and much improvement was obtained by the use of the jets. Another example of a case might be given where it was possible to carry about twice the boiler rating, or an increase in the heat release from about 20,000 to 40,000 Btu, by the use of jets and maintain less than a No. 1 Ringelmann smoke.

As to what the future may bring forth in the use of the stoker or the application of the principles involved, it can only be stated that it appears at present to be in a very active stage of its development. It has successfully replaced a number of both single- and multiple-retort underfeed stokers at various plants and also some chain-grate stokers. It is reaching toward the field of the large boilers. Its limitations in this respect are not so very apparent. It would be interesting to see the results of studies of its application in this field similar in nature and extent to past studies of other types of fuel-burning equipment.



Incinerator Plant, Cleveland, Ohio

Incinerators—Municipal, Industrial, and Domestic

By H. S. Hersey,[1] Cleveland, Ohio

The author reviews briefly the historical development of incinerator plants and discusses the trends in design in this country and abroad. Although industrial-waste incineration is mentioned briefly, and the incineration of domestic and institutional wastes is discussed in some detail, the greater part of the paper is devoted to the incineration of municipal wastes. Many problems and conditions governing steam production in incinerator plants are touched upon, together with general rules for estimating required incinerator-plant capacity in American communities. The author discusses in detail the design of municipal plants with complementary or auxiliary equipment employed. The latter part of the paper is devoted to the utilization of garbage and rubbish as fuel, with examples pertaining to furnace heat balance and furnace temperature.

In the process of the growth of the art of incineration, as related to such wastes as ashes, rubbish, and garbage, it has been recognized that garbage disposal involved problems so baffling that the disposal of ashes and rubbish became of secondary importance. Many methods of treatment and disposal of garbage have been tried, but few have been found that satisfactorily fulfill the requirements for thoroughly sanitary disposal of this noxious waste.

It is the author's purpose to confine discussions in this paper to incineration, as applied to the disposal of the previously mentioned classes of waste in municipal, industrial, and domestic fields; but as the greatest importance attaches to the municipal field, and the investment therein is by far the greatest, it will naturally receive major consideration.

INCINERATION OF DOMESTIC AND INSTITUTIONAL WASTES

Domestic and institutional incinerators cover the requirements for disposing of combustible waste in apartment houses, residences, hotels, hospitals, schools, and the like. For the most part, these installations handle both garbage and rubbish. The principal operating problems involve the maintenance of sufficiently high temperatures to insure against the discharge of obnoxious odors from the chimney, and the control of dust to prevent its being emitted to the atmosphere. There are two types generally considered of standard construction, one of which is manufactured of steel and cast-iron parts. The other type is that built with refractory linings, to which almost invariably gas burners are attached to insure high-temperature operation.

[1] Vice-President and General Manager, the C. O. Bartlett & Snow Company. Mr. Hersey attended McGill University and obtained his early mechanical training in the plant of Pillow & Hersey Manufacturing Company, Montreal, where he later became head of the department for manufacture of railroad-track bolts, nuts, and spikes. Later he entered the employ of the Dodge Manufacturing Company of Canada, Limited, as sales engineer, advancing to the position of manager at Montreal. He became associated with the C. O. Bartlett & Snow Company in 1912, first as its Canadian representative, but went to Cleveland in 1915 where he since has been actively engaged.

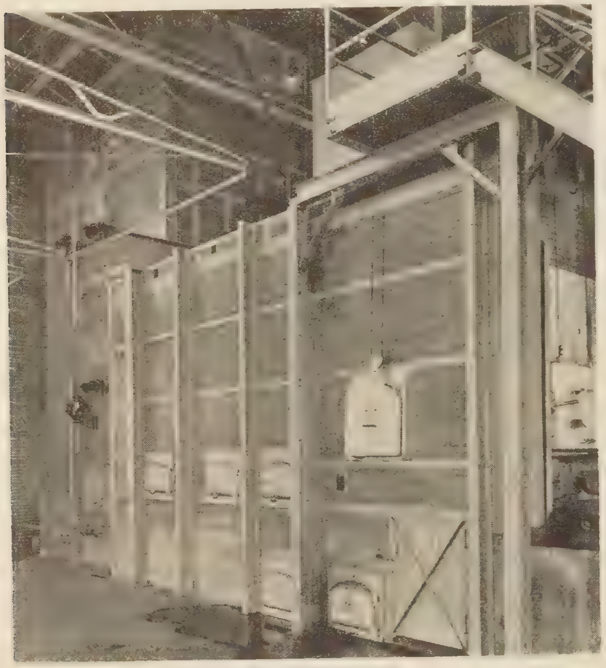
Contributed by the Fuels Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

The design, proportions, and general construction of these units are not greatly dissimilar to the practice employed in the municipal field.

Apartment-house incinerators are most frequently installed in the basement with the necessary vertical flue or chimney passing up through the building, which serves frequently as a chute for passing refuse to the incinerator from the various floors



FURNACE AND WASTE-HEAT BOILER IN INDUSTRIAL INCINERATOR PLANT

of the building. These chutes are fitted with necessary hopper doors at each floor level so that the refuse can be deposited therein by the tenants of the building.

Referring especially to domestic incinerators, unless accessory equipment, such as oil or gas burners, is employed to raise the temperature of the gases to a point where they will be completely oxidized and made nuisance-free, noxious odors are produced in the burning of garbage and any similar materials. Incinerators as usually installed by the general contractor, are of conventional construction, with a straight drop of the household waste into the furnace, with flue area, hopper-door openings, grate area, furnace setting, and wall thickness, governed by fire underwriters as to minimum size, but otherwise lacking in design and construction necessary to safeguard against either odors or dust.

Improvements now offered include hopper doors with dash-pot checks to prevent slamming. In their design care must be taken that they will not get out of order or retard the door closure to such a degree that under certain infrequent conditions there may develop a flash-back of chimney gases into the face of the person operating the hopper door. The firing door in the basement is most frequently interlocked with a check damper to prevent violent air inrush, and there is usually employed a rough control of secondary air over the fire by means of hand-operated louvers and an expansion chamber located on the roof to aid in trapping the dust. Unless great care is exercised, or secondary firing in the combustion chamber is employed, such trouble is to be expected, frequently resulting in the operation of this type of incinerator after dark to avoid detection.

This type of incinerator is open to improvement from the design viewpoint, but as it is sold almost on a pound basis, such improvement would undoubtedly contribute considerably to an increased cost, making it difficult to market it competitively. The indicated corrective would be for local health authorities to establish certain standards, otherwise there is not much hope for improvement over the present conventional designs.

INDUSTRIAL-WASTE INCINERATION

In an effort to keep abreast of the general movement for greater cleanliness and sanitation, industrialists are increasingly attacking the problems connected with a proper disposal of the accumulating wastes which result from their operations. These wastes are of widely different character, varying with the industry or product, and ranging from materials of high inflammability like photographic films and other light waste having high fuel content, to the other extreme of materials having high moisture content, such as wet wood bark resulting from paper-mill operations.

Many of these wastes have been successfully disposed of by incineration, but owing to the wide variations in characteristics, it has been required that incinerators be so designed as to adapt them to the particular duty.

While the woodworking industries have quite generally made profitable use and satisfactory disposal of their wastes by burning them under boilers, in many other industries, having burnable wastes and boilers, there are many factors that have to be considered before determinations can be made as to the advisability of making disposal through burning under boilers or through the employment of specially designed incinerators. All these problems, coupled with the necessity for making such disposal nuisance-free, call for an engineering service from those qualified by experience and a thorough knowledge of the art.

Incinerators in this field are occasionally charged from the top, but the more general practice is to charge the material to the furnace through the side doors, and without the use of mechanical chargers.

When incinerators are employed in banks, and other financial institutions, and are used for the destroying of papers which at one time were valuable, such as bonds and the like, extra care must be taken to insure that none of such papers are carried by the high-velocity gases and discharged from the chimney.

Industrial incinerators require individual study as, for example, when the material to be burned is such as film waste, with the attendant likelihood of explosions and the further necessity of recovering silver salts from the film ash. In some installations, there is also the problem of burning miscellaneous factory waste.

It is important in all such incinerators to have as large combustion chambers as practical, with a free opening beyond the primary fire and a negative pressure assured so that ample air will be drawn in to maintain an oxidizing condition for deodorizing. Such installations, of course, are not usually made without natural-draft gas burners or oil burners for this purpose. When handling highly combustible and lightweight material, difficulty is experienced in trapping the ash, even with combustion chambers of relatively large volume. In some instances, it might be found necessary to introduce a water spray or wet-type dust collector to insure a dust-free discharge from the chimney.

An interesting industrial incinerator with waste-heat boiler has recently been put into operation for burning materials having heating value up to 16,000 Btu per lb. Between 3 and 4 lb of steam is produced per pound of refuse burned, at rates varying from 16,000 to 22,000 lb per hr, and delivered to the steam headers of the main plant for processing work. The waste-heat plant operates 24 hr per day, but the steam production is only pos-

sible for three periods of approximately 6 hr each, as fire cleaning is required taking 2 hr three times per day. The plant is complete in itself including building, furnace, boiler, chimney, and auxiliary equipment.

To return to the major subject of this paper, and in order that we may have an understanding of comparative values in methods and equipment at present employed in refuse incineration, a little history of developments in the art seems in order.

To English engineers, municipal and sanitary officials, the greatest credit is due for the earlier developments in incineration. Like all important developments, they had their small beginnings. However, the studies made of these early applications produced data for further dealing with the involved problems by such men as Horsfalls, Meldrum, and Heenan who respectively contributed much to the development of the first incinerator furnaces, based on sound engineering principles, and in the year 1874, as shown by available records, the first such municipal incinerator for the destruction of mixed refuse was installed in Nottingham, England. This was followed two years later by a similar improved plant at Manchester. In America, the records seem to indicate that the first application of incineration was made in 1885 at Governor's Island, N. Y. This was a development made by an officer of the United States Army. The first American municipal plant was built in Allegheny City, Pa., during the same year.

As would be expected, the applications made in England and the benefits resulting therefrom were carried to the Continent, and eventually to this country. However, the first American designers failed to grasp the problems involved, and apparently were not informed of the technique being developed in England, and they merely attempted to burn wet garbage with the aid of coal or wood instead of mixing combustible rubbish and household ashes with the garbage.

In the early American installations, the general scheme of design was a brick chamber with a garbage-drying grate placed above a primary fuel-burning grate. A wet mass of garbage was gradually dried out by the burning of coal or wood on the primary grate, using natural draft, the volatiles in the garbage being distilled off in this manner, and the fixed carbon more or less consumed. The whole operation proceeded at low temperatures and slow burning rates. The net results were large volumes of highly offensive chimney gases and heavy auxiliary-fuel costs; and to cap the climax, violent protests from the suffering communities, all of which did not react favorably to those active in municipal affairs. Various modifications of design were used, such as a primary fuel grate from which the products of combustion passed over the mass of garbage, which was supported on a drying hearth at a slightly higher elevation than the primary grate, the gases finally passing into a gas-consuming chamber which also had grates for burning auxiliary fuel. In this gas chamber, the temperatures were supposed to be raised sufficiently to eliminate objectionable chimney odors. The results obtained in all of these early designs were unsatisfactory and quite generally the same.

Rapid obsolescence and maintenance of the earlier types of plants proved so high as to make incineration an expensive operation, as it is reported that for approximately 25 years following the installation made in 1885 on Governor's Island the plants built were operated with only indifferent success, and in many cases flat failure. These early plants are stated by one authority to have been about 180 in number, of which 102 were abandoned on account of expensive operation or insufferable nuisance to the community.

The first real recognition given to the high-temperature type of furnaces in this country was about 1906, when an installation was made at Staten Island, N. Y., built to burn a mixture of garbage, rubbish, and ashes. It is doubtful, however, if the engineers who designed or selected this type of plant fully realized that the character of English mixed refuse and American mixed refuse differed so radically in characteristics; however, their first attempt in this country demonstrated the fuel value of a mixed collection.

In about the same year at Westmount, Quebec, Canada, there were installed Meldrum type furnaces, together with boiler installation and electric generators. Later, Heenan furnaces of approximately equal size were added, together with additional boilers and electric generators. This plant was designed and prepared under specifications of the eminent power-plant engineers, Messrs. Ross and Holgate of Montreal, and their interest, as well as that of the community, kept it in efficient operation until about four years ago, when it was decided to accept the rate of a local electric-power company for furnishing electric current to the householders, as well as for street lighting in Westmount, continuing only the incinerating operation.

Following the Staten Island and Westmount plants, others were built in Vancouver, B. C., Seattle, Milwaukee and Buffalo, all of these being equipped with waste-heat boilers. American builders continued to approach the problem with very much the same thought in mind as the English, namely, that of employing the heat value of a combined collection of garbage, ashes, and rubbish in order to produce high temperatures to oxidize the products of combustion, employing, in this connection, large and properly proportioned combustion chambers, wherein the gases were held and mixed at high temperatures until there was complete oxidation of combustible elements, and employing for the travel of the gases ducts of such area as to slow down the velocities of gases to a point where the entrained dust particles would be deposited, which, together with necessary baffles and traps, proved to be practical of application for the minimizing of odors and dust.

The so-called mutually assistant cell type of furnace appeared in England about 1893 and has influenced both British and American design ever since. This type of furnace will be described more in detail later in this discussion. Incinerator design and construction in the United States and Canada, during the past twenty years (as hereinafter set forth), has shown development from early English practice, to better adapt incinerators to American conditions as related to the composition of materials to be incinerated, and as well the methods of collection, but with a tendency to adhere to the fundamental principles of the English practice.

In England, the general practice still favors a combined collection wherein ashes as well as garbage and rubbish are placed in the same vehicle, and so transported to the disposal plant. In America, the general practice is to collect the ashes separately, disposing of them by dumping; and if the garbage and rubbish are to be disposed of by incineration, their collection and transportation to the plant are made together. If, however, as still obtains in some cities, the garbage is disposed of by a reduction system, then these wastes are collected separately, and the rubbish is either (1) incinerated, or (2) dumped and used as fill, frequently with covering of earth. By far the most general procedure, however, is to collect and dispose of the garbage and rubbish together; and, when containing ashes in an amount not exceeding approximately 5 per cent, this combination is readily disposed of by incineration.

Several of the Pacific Coast cities, including San Francisco, still dispose of garbage and rubbish by the fill-and-cover method.

Aside from what has just been stated about the differences in collection methods, the refuse (garbage and rubbish) in America compared with that of England carries more waste matter from the table and shops, of vegetable and animal origin, and further

there is a greater quantity of combustible material consisting of paper, cartons, wood, and the like, resulting from the greater number of newspapers in circulation, and also the use of combustible materials in the packaging of our products, all tending to produce a high calorific value.

In England and certain continental countries, with refuse high in ash content, the tendency in incinerator practice has been to employ screening and other classifying equipment for the removal of fines, inert material, metals and glassware, and the production of a better fuel. With this high-calorific material, and through the employment of boiler-plant equipment in connection with the incinerator, they have steam for a by-product, and frequently find use for the clinker in the production of concrete aggregate and clinker asphalt.

In this country and Canada, rarely has it been attempted to make incinerator operation revenue producing, either through the reclamation of salable materials, such as metals, rags, bones, and the like, or through the production of steam or electric energy, although methods and equipment have been developed and employed in a few instances for accomplishing these results.

The economy of the American method of disposal has been partially predicated upon the savings accomplished through low hauling costs by locating the plants near the centers of production areas and also by substituting the mixed collection service for the former separate collection system.

Because many engineers inspecting modern high-temperature incinerators, not employing boilers or electric-energy units, have a feeling that something should be done to utilize the heat and power so generated, it might be well to deal with some of the factors confronting the engineering and other municipal authorities, in selecting the type incinerator to be used and in judging of the economic values to be expected from the production of steam and electric energy.

In connection with municipally operated plants contemplating steam- and electric-power production, it will be found that one or more of the following four conditions may obtain, and operate to discourage the introduction of such utilization features, and to confine the operations to refuse destruction, with attention concentrated upon sanitation and minimum cost:

1 Difficulty encountered in making advantageous use of steam or current at or near the incinerator site. And even where such uses are found, the demand for either steam or current or both, is such as can with difficulty be supplied for peak or even average requirements, because of:

2 Lack of uniformity as to quality and dependability as to quantity of the refuse, due to variations in production, either seasonal or resulting from extremes of cold and wet weather.

3 Greatly increased capital investment required for a steam- and electric-generating incinerator, as compared with one designed solely for use as a destructor of refuse.

4 The presence of a utility company, holding a franchise from the municipality for the generation, sale, and distribution of steam and/or electric current, with the opposition to be expected therefrom to competition from the municipality.

With the foregoing general observations, and relying upon the general acceptance of the principle that the first and the controlling consideration of a disposal plant should be that of sanitation, the author will leave further details of steam and power development to a later part of this paper and will proceed to a discussion of the conditions generally obtaining, and the practices currently accepted and approved for meeting them.

The wastes which municipalities deal with through collection and disposal are garbage, ashes, rubbish, street sweepings, night soil, and dead animals. The author is assuming that the composition and characteristics of each of these wastes are generally recognized, and that detailed descriptions of them are not at this time necessary. We are concerned at present only with garbage and rubbish and with their disposal by incineration.

For economical incineration, it is required that the rubbish be in sufficient quantity to furnish the necessary heat units for the combustion of the garbage. If there is not sufficient of this available, then the necessary heat units must be supplied by the use of coal or other fuel.

Rules of thumb have been developed for roughly determining quantities of garbage and rubbish produced in the average American city, among which are the following:

There are 200 lb of garbage per capita per year, or a total annual tonnage equal to 10 per cent of the population. Another rule for figuring the garbage production is $^1/_2$ lb per capita per day; but it is the author's judgment that this latter is somewhat lower than prevails, especially in the North.

The quantity of rubbish produced varies more widely than garbage, but a fair average for American conditions is to figure rubbish at about 50 per cent of the garbage tonnage. Allowance, however, must be made for the presence in rubbish of about 10 per cent of noncombustible material. In some communities, records are kept which indicate higher-tonnage rubbish collections, but in these cases it is fair to assume the collections include a higher percentage of such materials as metals, miscellaneous junk, old stoves, bed springs, and the like.

Capacity Required for Refuse-Incineration Plants

In determining the size of incinerators required to dispose of a city's refuse, care should be taken to insure that adequate capacity is incorporated into the plant, or that provisions are made for additions thereto, so that as the city develops and the production of refuse increases, future quantities may readily be disposed of without any very great additional capital expenditure. Further, it is necessary, in determining the plant size, to be sure that provision is made for taking care of peak loads, for, as is well known, there are seasonal variations in the production of both garbage and combustible materials. Sometimes, in cities, where expositions are held or other unusual activities take place, there is such an increase in waste production as to require considerable oversize of plant to take care of this added burden.

Therefore, a fair rule to follow, for the determination of the proper size of refuse-incinerator plant, would be to divide the population by 1000, which would give the size of plant in tons per 24 hr adequate to take care of the needs of a city, including peak seasonal garbage production and make some provision for future additional population. For example, a community of 100,000 people should construct an incinerator having a rated capacity of 100 tons for a period of 24 hours. This will provide for the peak garbage production in the late summer and fall and also allow about $33^1/_3$ per cent excess capacity for future increase in population.

Costs of Disposal by Incineration

The costs of operating an incinerator plant, where sufficient rubbish is available, and where air preheaters are used as part of the equipment, will be free of any charge for auxiliary fuel, providing the characteristics of the mixed refuse conform to those of refuse as collected in the average American city, namely, garbage by weight 65 per cent, combustible rubbish by weight 35 per cent, and having an average combined moisture content approximating 50 per cent. This proportion of garbage and combustible rubbish can be collected in the average city if proper ordinances are passed and enforced. Other costs should include capital cost, depreciation, maintenance, amortization, labor, power, water, and the like.

It would be useless to set forth in a paper of this sort even an average cost taken from the records available, as the variation is so great as to be misleading. No doubt a great deal of the discrepancy is attributable to the variations in cost-accounting and reporting methods of the various cities. In certain cases, records are kept by department employees who are not interested in their correctness, and in other cases the reports reflect the prejudice of the department keeping these records, or even the influence of the incinerator manufacturers. Labor costs in one section of the country compared with others—especially of plants operating in the South with those in the North—alone account for great discrepancies in the cost of disposal. It is therefore necessary that any per-ton cost advanced by a municipality or incinerator manufacturer should be given thorough analysis before accepting it for the purpose of comparison with costs in other cities.

In order to support this statement as to cost, it is interesting to note that the Civic Development Department of the Chamber of Commerce of the United States in 1931 made a survey of refuse disposal in 154 American cities which showed average cost of disposal by incineration of $1.26 per ton; however, this is practically meaningless inasmuch as the reports analyzed showed variations ranging from 23 cents per ton to $4.25 per ton. Obviously when the difference in the operating cost is so great, the figures are not comparable.

It may be of further interest to note the direct comparison of operating costs between incinerator plants of like rated capacity, under the same controlling supervision; one where the refuse is placed in the charging containers by manual labor, the other plant employing refuse-receiving pits from which the material is raised and placed in crane charging hoppers directly over charging containers. In this connection are mentioned the Wellington incinerator at Toronto, Canada, and the Symes Road destructor of the same city. The former is manually charged, and the latter crane-operated. Both plants have a capacity rating of 400 tons per 24 hr.

Wellington Plant (manually charged):	
Labor cost	$1.40 per ton
Total cost	1.60 per ton
Symes Road Plant (crane-operated):	
Labor cost	$0.83 per ton
Total cost	0.92 per ton

These results are from the published report of operations of the Department of Street Cleaning of the City of Toronto for the year 1936.

Modern Incinerator Plants

In order to present a general description of the arrangement and equipment of a modern incinerator plant, the author gives descriptions of the major units of typical plants, and of their functions.

Weigh Scales. It is usual to employ weigh scales at the entrance to the plant, whereby loaded collection vehicles passing over them are weighed and the records tabulated. In the case of smaller cities, this is not employed as it is an added expense, and the weigh clerk and office requirements have to be provided.

Receiving Pits. In a plant using cranes for the rehandling of the mixed refuse, there is provided a receiving pit into which the collection vehicles dump the mixed refuse. In plants designed for 24-hr furnace operation, the capacity of the receiving pits must be large enough to store mixed refuse for at least 16 hr operation of the furnaces, since the collection deliveries are usually made within a period of 8 hr. The plants having receiving pits for the mixed refuse require that the grab-bucket cranes handle the material from the receiving pit to charging hoppers over the furnaces for final introduction into the furnace chamber.

Storage Floors. Many plants not employing the receiving pit are provided with a ramp to a dumping floor which is at an elevation above the storage and charging floor. With such an arrangement, the mixed refuse is fed by hand to the charging holes or charging machines of the furnace chambers. Some storage floors are provided with service cranes to assist hand feeding. The same storage capacity, namely for 16 hr operation, is required in this type of plant in order that the furnaces may operate for 24 hr.

Hillside Sites. Plants are sometimes located on hillside sites, permitting vehicles to drive in off the main thoroughfare without the use of a ramp; and in some instances they are found advantageous due to lower expense for roadways compared with the ramp and other construction details.

Direct-to-Furnace Plants. In smaller plants, it is frequently the case that the collection vehicle drives directly into the building on the charging floor and the refuse is dumped directly into the charging holes of the furnace chamber. In plants designed in this manner, the furnace capacity should be large enough to keep up with the rate of delivery of mixed refuse. These plants are seldom operated continuously during 24 hr.

Salvage Plants. A few plants in this country employ facilities such as picking belts with magnetic pulleys for the purpose of picking off paper and rags, and for the removing of ferrous metals. In such cases, the picking is done by hand labor, and it is necessary to provide bailing equipment for the bailing of tin cans and papers.

Charging Hoppers. In plants with receiving pits and grab-bucket cranes, the mixed refuse, as previously stated, is deposited by the grab bucket into charging hoppers. These charging hoppers are on a charging floor directly over the furnace chambers. Each hopper is divided into sections and each section is open into the top of the charging container of the charging machine, which is directly below the charging floor and over the top of the furnace chamber.

INCINERATOR FURNACES AND ACCESSORY FUNCTIONING UNITS

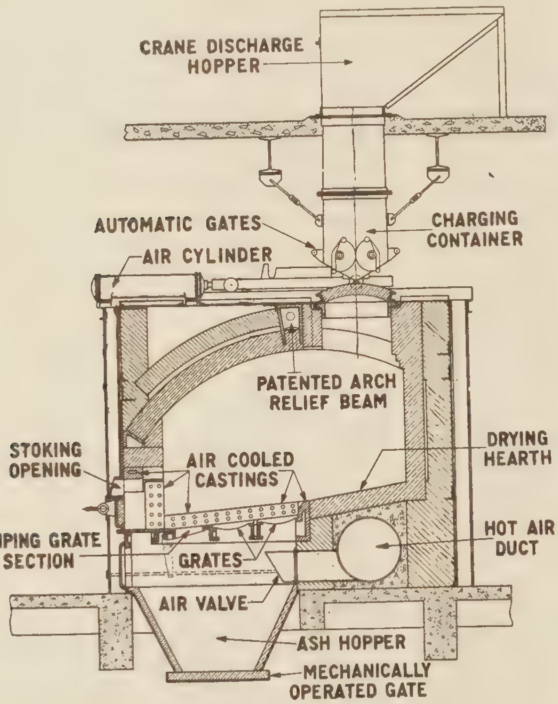
In all types of incinerator-furnace construction now offered by reputable manufacturers, there is one principle common to all, namely, that charges of wet material do not drop directly onto the burning grates, but are retained on drying grates, drying hearths, or in drying baskets until the contained moisture is sufficiently evaporated to make the refuse burnable, after which it is drawn onto the burning grate.

The furnace chamber is that part of the incinerator structure which encloses the burning grates and drying hearth, or drying grates or basket. A number of incinerator manufacturers build furnace chambers after the English design of mutually assistant cells; that is, the burning grates are divided into cells by the installation of castings approximating 8 in. in height above the grate level. Typical of this design is a furnace having four cells so divided off by castings, all enclosed in a refractory-lined chamber with an ash pit for each cell placed below the grate level, and with provision for admitting forced-draft air to each cell, separately controllable. On the stoking side of the furnace chamber there is a guillotine-type door for each cell provided with an opening therein, through which the stoking of the fires and partial cleaning of the grates is accomplished. The guillotine doors are raised for finally cleaning the grates following the burning down period. The refractory lining of the furnace chamber is provided with proper insulation. Steel plating and the necessary buckstays form the outside construction of the furnace chamber. The drying hearths are usually of refractory construction, built

with a slight slope toward the burning grates. Drying hearths sometimes are constructed as drying grates of stationary cast-iron grate sections in lieu of refractories.

In the mutually assistant-cell type of furnace, each cell has a charging opening in the main arch, through which the charges of mixed refuse drop by gravity onto the drying hearth. In cases where material is delivered into the furnaces directly from collection equipment, it is usual that the charging openings are extended to the charging-floor level and are closed with a refractory-lined charging-hole cover.

In the larger plants, where material is handled to the furnaces by cranes from receiving pits, or fed by hand from storage floors, charging machines are provided, one for each cell. These charging machines consist of a refuse-charging container with hopper bottom or sliding gates, having a charging carriage with



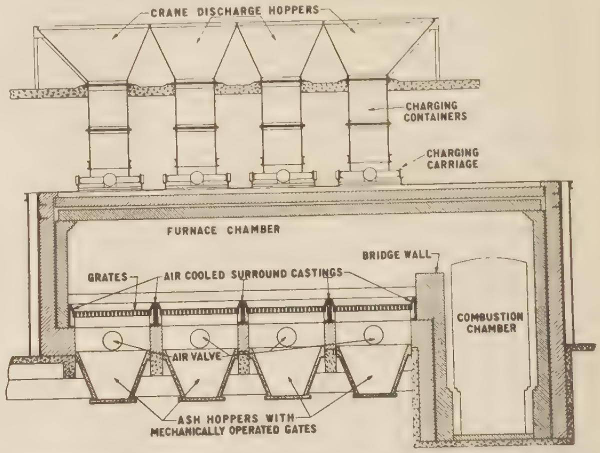
Cross Section of Incinerator Furnace Chamber

rollers operating on structural-steel supports and rails. The carriage is actuated either by a compressed-air ram, or an electric motor, or by hand-operated mechanism.

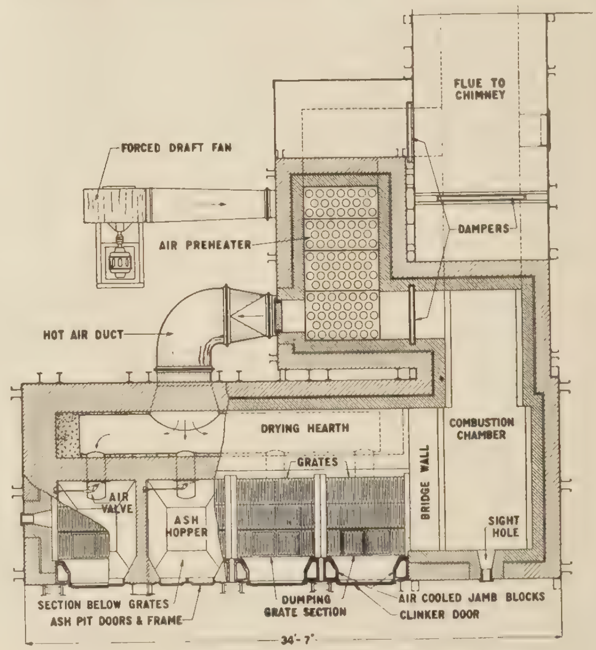
The actuating mechanism of the carriage is under the control of the stoker, and the charging-hole cover, which is refractory-lined, opens or shuts with the travel of the carriage, allowing the charge of refuse to fall by gravity out of the charging container through the charging hole and onto the drying hearth in the furnace chamber below. Upon the closing of the charging opening, the charging container can be refilled with refuse by the cranes or charging-floor man, and is again ready for further operation by the stoker when, in his judgment, the fire requires another charge.

The advantage claimed for the mutually assistant-cell type of furnace chamber is that draft control and fire control are individual and separate for each cell; that fires can be cleaned, one cell at a time, while normal burning rates and temperature on all other cells are maintained during this operation. Further, that if it so happens fires are in bad condition in one or more of the cells, then the fires in the others will assist in reestablishing in such cell or cells the proper burning rates and temperature.

Some types of furnace chambers do not employ the mutually assistant-cell principle, and in some cases these are provided with drying hearths or drying grates on which the refuse is retained until such time as the greater part of the moisture has



Longitudinal Sections of Furnace and Combustion Chambers



Plan of Mutually Assistant Furnace

(Four-cell, mutually assistant-incinerator furnace and combustion chambers showing drying-hearth grates, ash hoppers, flues, preheaters, and fan, with air ducts and draft control.)

been driven out. Usually these furnace chambers are also refractory-lined, and they may be either rectangular or circular in construction. They are most frequently charged from the top and rarely have more than two charging holes per furnace chamber, and sometimes only one.

A type of furnace-chamber construction not refractory-lined has been installed in many cities. This is built of boiler plate with water legs and crown sheet, somewhat like a locomotive-boiler furnace. The refuse is retained directly above the burning

grates in tubular water-cooled baskets until properly dry, and stoked down as required. One or two charging holes are generally provided for each chamber in this type of furnace.

Furnace-chamber volumes usually run from 9 to 10 cu ft per ton of furnace capacity per 24 hr. Burning rates range from 70 to 85 lb of mixed refuse per sq ft of burning grate per hr, this being normal capacity. Overload rates of 100 lb per sq ft per hr can be maintained for indefinite periods. The rates referred to are all based on the use of forced draft.

Combustion Chambers

Combustion chambers are refractory-lined and are placed either back of, or at the end of the furnace chambers. The purpose of a combustion chamber is twofold:

1 To provide a means of finally mixing the products of combustion generated in the furnace chambers with available oxygen, thereby effecting complete combustion at high temperature.

2 To provide a space of ample volume and area so that the gas velocities will be sufficiently lowered to deposit fly ash, dust, and solids.

In practice, a minimum temperature of 1250 F and maximum temperature of 2000 F, with an average not less than 1450 F, is required for the combustion chambers to operate satisfactorily. Under these conditions it will be found that all products of combustion are completely oxidized, and the gases discharged from the furnace chimney will be absolutely inoffensive.

To accomplish the proper mixing of gases and to insure the deposit of fly ash, dust, and solids, it is usual to construct the combustion chambers having volumes ranging from 12 to 15 cu ft per ton of 24-hr rate of incinerator capacity, with such cross sections of the combustion chambers as to limit the gas velocities to 15 fps.

Heat release in combined volume of furnace chambers and combustion chambers is from 10,000 to 15,000 Btu per cu ft per hr.

Flues

Flues as used for the passage of gases from the combustion chambers are refractory-lined, and in practice require cross-sectional areas large enough to limit gas velocities to 25 or 30 feet per second.

Air Preheaters

In burning refuse, rapid ignition is of great importance to secure capacity and maintain temperature; further, as there is a large amount of moisture required to be evaporated and refuse to be heated to the point of ignition, preheated air is of unquestionable value. It is a well-known fact that oxygen in the air will unite with carbon more readily when either or both are preheated. In refuse furnaces, combustible material is heated on the drying hearth by radiant heat from the furnace walls and arches and by radiation and convection from the fuel bed itself, and the air is heated by means of a preheater, using for this purpose such portion of the gases from the combustion chamber as in the judgment of the operator is required to meet any condition within the furnace. The proper use of preheated air will make refuse combustible that would not otherwise burn without additional fuel. Furthermore, since preheated air occupies a larger volume per pound than air at room temperature, it follows that a given weight of preheated air is distributed more advantageously throughout the combustibles in the furnace, resulting in less total air required for combustion, which reflects in higher furnace temperatures.

Construction of preheaters varies according to the temperature of flue gases required to be passed through them. For example, in a plant not having waste-heat boilers, or where the products of combustion pass through the preheater prior to the boiler setting, the temperatures of the gases passing through the preheater are quite high. On the other hand, if set after a waste-heat boiler, any conventional type of preheater for boiler service may be used. Preheaters set without boiler or ahead of boilers must be of a high-temperature type, preferably vertical tubular down-draft, with hot gases passing inside the tubes from top to bottom. It is usual that the forced draft make at least two passes through the preheater on the outside of the tubes. Heat-exchange surfaces are encased in steel boxes in order to minimize or prevent leakage.

Preheated-air temperatures in practice usually range from 300 F to 400 F, and in order to proportion preheaters so that these temperatures may readily be attained, exchange surfaces will be found to run from 7 to 8 sq ft per ton of furnace capacity per 24 hr. A preheater proportioned in this manner can usually develop the required temperature by passing 40 per cent or less of the total products of combustion through the preheater, set without or ahead of waste-heat boilers.

On account of the importance attached to preheated air as related to the heat balance of the furnace, especially in the burning of very wet refuse, further consideration on this point is given later in this paper.

To the best of the author's knowledge, the first application of preheated air to a refuse plant not employing steam-generating units was in connection with the installation made in Toronto, Canada, in 1915 at the Don incinerator; and because of this application, patents were applied for and issued, covering a design wherein the gases from the combustion chamber passed downward through the tubes.

Expansion Chambers

Expansion chambers are refractory-lined structures designed to reduce the final velocities of gases prior to passing to the chimneys so as to precipitate any dust, fly ash, or other solids that may have escaped the combustion chambers. Expansion-chamber volumes in practice range from 10 to 14 cu ft per ton of rated furnace capacity per 24 hr. Cross-sectional areas should be such as to reduce gas velocities to 10 fps.

The first application of expansion chambers which came to the author's attention was the installation made in 1931 at Montreal, Canada.

Chimneys

Incinerator chimneys must be capable of handling gases up to 1000 F, which temperature sometimes prevails at the base of the stack when burning mixed refuse. In burning highly combustible rubbish, chimney temperatures may be expected to be as high as 1800 F, and therefore, for rubbish incineration, should be lined and otherwise constructed so as to withstand this condition and function continuously.

Chimneys to serve incinerators are customarily built of an outer radial brick shell, with refractory lining throughout the entire height of the chimney column. The more general practice, in relation to such linings, is that they be independent of the column and completely self-supporting. Experience has developed a practice whereby the linings are corseted with steel straps, both belted and vertically disposed, and so arranged as to be interconnected, all for the purpose of insuring against failure.

The first application of such a corset, coming to the author's attention as applying to incinerator installations, is the Wellington Incinerator at Toronto, Canada. Chimney areas will usually be found in practice to equal 20 to 25 per cent of the burning-grate area served, and the heights will run from 100 to 175 ft.

Dampers

Dampers are regularly furnished and installed to control the

flow of gases in the main exit flue from the combustion chamber, the entrance flue to the preheater and the exit flue from the preheater (when preheaters are set ahead of boilers), and occasionally in the main flue connecting the expansion chamber to the chimney. These dampers are subjected to quite severe duty, are necessarily built to withstand high temperatures, and are most frequently constructed with special high-temperature alloy castings with refractory surfaces in the path of travel of the high-temperature gases. Occasionally they are of water-cooled design, but more infrequently of all alloy, high-temperature, or special ferrous material. Generally, they are of the guillotine type, counterbalanced and/or winch-operated.

When control dampers are used in connection with preheaters which are set behind waste-heat boilers, they need not be constructed to withstand high temperatures. When waste-heat boilers are used, high-temperature dampers are generally installed in the flue entrance to the boiler.

Ash-Handling Equipment

In the smaller plants, ashes and clinkers are generally raked off the stationary grates onto the firing floor and later shoveled into wheelbarrows and spoiled outside the incinerator building. In the larger plants, ash and clinkers are passed through dumping grates within the furnace chamber directly into ash hoppers located directly underneath the grates, and the quenching of the ashes takes place within such hoppers.

Ash hoppers are usually accessible by means of ash basements which permit of trucks driving directly through the plant underneath the respective hoppers; or if industrial cars are used, the contents of the hoppers are either taken to a remote point by the cars to be used as fill, or discharged into push-button-controlled ash-skip hoists or onto platform elevators, and by these means raised and discharged into ash bins or other receptacles, generally outside the building, from whence the ashes are transported for final disposal at convenient intervals.

Furnace Auxiliaries

Auxiliary machinery generally includes, in the large-size plants, electric traveling cranes with grab buckets, forced-draft fans, air compressors, and temperature and draft instruments. Crane capacities are generally $3^1/_2$ to 5 tons, employing grab buckets having capacities of $1^1/_2$ to 2 cu yd. Forced-draft fans should be capable of supplying as much as 5 lb of air per lb of mixed refuse burned, and are usually direct-connected to an electric motor. Air compressors generally must supply not less than 10 cfm of actual free air per charging machine served.

Temperature-control instruments, including recording and indicating pyrometers, are usually installed for observing combustion-chamber, preheated air and chimney temperatures, and draft gages for determining the forced and chimney draft. The use of control instruments has, in many instances, been unnecessarily elaborate, the essentials being only indicating pyrometers for registering combustion-chamber and preheated-air temperatures.

In small plants, and where close supervision prevails, operations can be successfully carried on without any instruments.

Stoking and Cleaning Fires

Mechanical stoking of incinerator furnaces has not as yet reached a successful solution. A man on the cool end of a stoking tool is still the accepted means of moving material onto the burning grate and spreading the fire. Manual labor is also employed for fire cleaning, although the efforts attached to this task have been lessened in the more recently constructed larger plants equipped with dumping sections within the furnace chamber. These dumping grates discharge ash and clinker to ash hoppers; but even with the apparatus povided, the labor of breaking clinkers on the grates and passing the residue through the dump opening is considerable. In the smaller plants with stationary grates, the clinker is required to be broken by slice bars and is usually raked out by manual labor onto the firing floor or into ash skips. The real reason for the continuation of hand stoking is because of the uncertainty of the quality of the refuse handled, as it is never the same from season to season, or even from one charge to another, varying in heating value, moisture, ash content and mechanical condition.

Steam Production in Incinerator Plants

With further reference to previous discussion in this paper relative to steam production, the author has to state that when the visiting engineers referred to, or other technically trained men, first view a modern incinerator plant not equipped with steam-generating units, and after gazing into this inferno, and noting the large volume and rolling action of the gases at temperatures maybe as high as, possibly, 2000 F in the combustion chamber—all of which is truly impressive—they all ask the same question: "What do you do with all that heat?"

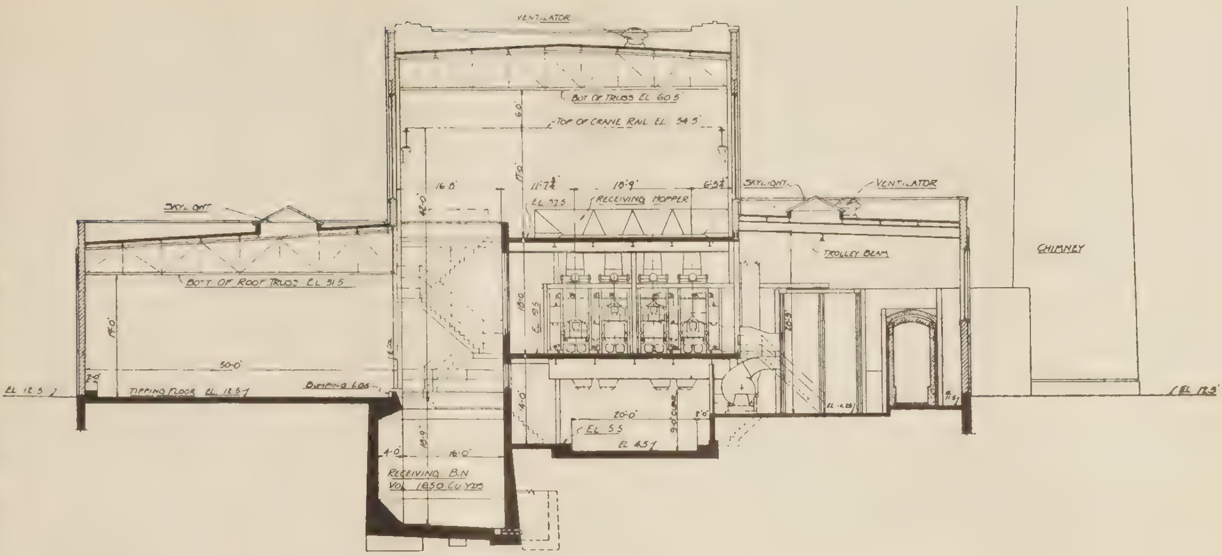
In America, incinerator plants, in which full use is made of the heat developed, are the exception rather than the rule. However, as previously covered, in most of the high-temperature plants there is utilization of some of the heat values by employment of the combustion gases for heating the air for combustion. When our visitors are informed that, except for such auxiliary uses, the tremendous quantity of heat which they have just observed is being wasted up the chimney, with considerable concern they remark on the apparent lack of efficiency, and unless they inquire further into the facts, or are furnished with an explanation of the deterrent factors which enter into the problem, they are apt to classify incinerator practice as a criminal waste of the taxpayers' money.

After complete combustion has been accomplished, there is, of course, no reason why the developed heat cannot be utilized for making steam, as sanitary conditions can be maintained throughout the operation, even though the flue gases would be cooled down by their passage over the heat-absorbing surfaces of the steam boiler, providing, however, that complete oxidation at high temperature has taken place in the combustion chamber before contact is made by the gases with the cooling surfaces in the boiler.

In England, and on the Continent, nearly all the large incinerator plants are equipped with steam boilers and power-plant equipment for the production of electricity, employing the energy for pumping of water, sewage, or other municipal or private power purposes. Compared with Americans, Europeans appear in general more inclined to make use of all possible savings, whether it be in incinerator plants or other operations from which values in the form of by-products may be obtained; and American people are regarded by Europeans as notorious for their apparent wastefulness, not alone in incineration, but with reference to such resources as farms, mines, oil, and water power.

However, the primary purpose of an incinerator plant is to destroy refuse in a sanitary manner, and this must be accomplished every day throughout the year that collection of refuse is made, so that the question of power development is, and, to a great extent should be considered, secondary.

There are a number of steam and power-development incinerator plants in America, some of which have applied the steam to the servicing of municipally owned asphalt plants. Others have been able to sell their steam or power in quantities to public utilities without entering into direct competition with them, while still others use the steam for no other purpose than for the operation of the equipment which is auxiliary to the func-



Typical Cross Section of an Incinerator Plant

tioning of the incinerator furnace. However, the amount of power necessary for the operation of this auxiliary equipment such as forced-draft fans, compressors, and the like, is very small, and in most instances would be cheaper if purchased from a public-service company than when produced by the incinerator, if the cost of extra equipment, labor charges for skilled personnel, maintenance, necessary amortization, and all like charges are included in the cost of production.

Probably the outstanding installation wherein the use of steam is profitably employed is at the rubbish-burning incinerator plant of the City of Rochester, N. Y. It so happens that their incinerator plant is located adjoining their garbage-reduction plant, and in the process of reduction, large quantities of steam are required for the processing; and such steam as is metered to the reduction plant is credited to the operations of the incinerator.

Unique also is this reduction plant, in that it is in close proximity to the plant of the Rochester Gas and Electric Corporation whose steam lines are also connected to the reduction steam mains, so that when steam is required in excess of that produced by the incinerator plant, they are able to procure as much steam as is necessary for covering their peak requirements; and in this manner, fluctuating quantities of rubbish coming to the incinerator, and the varying qualities and conditions of same do not affect continuity of operations in the reduction plant. The existing incinerator plant is inadequate to handle the production of rubbish in Rochester, and a contract has recently been awarded for an additional incinerator plant employing steam-generating units. This may have the effect of producing sufficient steam so that the reduction plant will not be required to purchase steam at any time from the public-service company, except in cases of emergency.

It is important to note that in the design of a steam-producing incinerator plant, there are involved certain difficulties not encountered in the design of a coal-burning boiler plant. In the first place, a coal-burning plant is designed to use a fuel having quite definite characteristics, and of practically uniform chemical constituents, and which can be purchased in any required amount, making it quite easy to meet any definite load or variation of load which may occur during any period of operation. In the case of a steam-production incinerator plant, the designer is limited in his guarantee of the amount of steam to be produced by what he estimates can be produced under the worst conditions of operation, when the refuse may be extremely wet and only a minimum quantity is available. At the same time, he must provide incinerator capacity to meet the requirements for maximum production of refuse. From what has been said about the design of steam-producing plants, it is evident that if the designer is considering a plant to meet a steam demand exceeding the possibilities under the aforesaid adverse conditions, he must provide in his plant means for producing steam by auxiliary coal, oil, or gas firing in separate stand-by boilers, or by incorporating auxiliary grates or burners for such auxiliary fuel in connection with the boilers set in with the incinerator.

Another consideration which must be taken into account is the fluctuation in the steam demand itself, which has no relation to fluctuations in the fuel, and stand-by equipment must be provided to meet rapidly fluctuating demands. Even though the average load may be balanced by the average amount of refuse available for fuel, the designer is likely to be further handicapped because in all probability the minimum of available fuel will sometimes coincide with maximum steam demand.

It is for such reasons as these that designing a steam-producing incinerator plant is not simple; for where a definite capacity must be guaranteed, which is impossible with the minimum quantity of available refuse, a large investment is necessarily required to be made for stand-by equipment.

When the steam demand is small and steady enough so that more steam than is required can be produced at any time by the refuse available, the problem is comparatively simple, as it resolves itself into the selection of a boiler with sufficient heating surface to produce the necessary steam. Inasmuch as under these conditions more flue gas is produced than is necessary for steam production, the economical design would be a boiler only large enough to make the necessary steam, and so set and provided with flues that the excess flue gas produced can be by-passed directly to the chimney. By this arrangement, the necessary furnace capacity can be provided for the maximum collection, and at the same time the boiler will be ample for the steam demand with only a minimum of investment.

If a steam-producing incinerator plant is to be considered, a complete study should be made of all relevant conditions and

problems. As previously indicated, it should be viewed from the standpoint of whether or not the results when accomplished will justify the investment. If this is settled in the affirmative, then the selection of furnace and boiler equipment, together with electric-generating units can be made to meet the conditions. Included in the study must be a careful analysis of the maximum, minimum, and average quantities available, as well as the quality of the refuse to be burned—with particular reference to the fuel value. This latter will involve the determination of the noncombustible and moisture content of the refuse. After these points have been settled and it is decided to proceed with the designing of a steam-power incinerator plant, calculations can be made as to the furnace design to provide the capacity necessary to take care of the maximum collection of refuse, and combustion-chamber temperatures can be predicted within definite limits, as can also the quantity of flue gas available for steam production.

Boiler sizes and design must be suitable for the quantity of flue gas available at the predicted temperature. Boilers are generally of the water-tube type, of various designs and arrangements of baffling. Natural draft or induced draft may be used, according as they lend themselves to the conditions obtaining. Boilers may be set so that one particular boiler operates on one particular incinerator, or they may be set so as to take gas from a main flue which will be a mixture of gases from several incinerators. Preheaters, as usually set in the English practice, take flue gas which has passed through the boiler.

While it is not the purpose of this paper to follow through any one particular problem in design, it must be quite evident that any project must be considered individually, so that the selection of plant equipment and plant arrangement therefore may be suited to and meet all controlling conditions. The one guiding rule, which should be borne in mind by the designer, is that he should balance investment against resulting values.

Obviously, the steam that may be generated by the burning of a pound of refuse varies with the heat value of the material; and while the heat value of the refuse on a dry basis may be nearly constant, weather conditions may cause great differences in the day-to-day evaporation results. Theoretical calculations show that overall efficiency of boiler furnace and grate may vary from a low of 25 per cent to a high of possibly 65 per cent, corresponding to approximately an F & A evaporation of 0.5 lb at 25 per cent efficiency, and approaching 4.5 lb at 65 per cent. Overall efficiency of boiler furnace and grate is expected to be not less than 50 per cent for good practice, but, of course, variations up and down are to be expected, due to changes of the refuse or relative amount of boiler heating surface, etc. The great variation in theoretical figures indicated above is due to the fact that the lower figure is based on refuse of poor quality, and the higher figure on a relatively higher fuel value.

Available data from English practice, when burning refuse such as is usually collected in that country, indicate plant evaporation on the F & A basis ranging from 0.8 to 3 lb of steam per lb of refuse burned. From records of operations at Paris, France, it appears that about 1.1 lb of steam is produced per lb of refuse. Very few data of the results of American practice are available, but such as we have show evaporations ranging from 0.7 to 1.5 lb.

With reference to most of the installations in America for incineration, coupled with steam-power development, it is my belief that a much better showing of evaporative capacity could be made if the gas passages and heating surfaces in the boilers had been made large enough to develop the full possibilities of the plant.

In concluding this part of the discussion, it may be stated that the trend in English and European designs is to incorporate steam-producing equipment in municipal incinerator plants, which indicates an engineering judgment that the resulting economies justify the investment. American conditions, on the other hand, in most cases do not appear to warrant the investment in steam boilers and power-producing equipment, although there are exceptions, as brought out by the author, wherein there were justifying economies.

Mixed Refuse as Fuel

As previously stated, garbage and rubbish as generally produced in American cities, when mixed together as collected, will have sufficient fuel value, and be in such condition that combustion can be supported at temperatures sufficiently high to insure against the emission of objectionable odors from the incinerator chimney. Many studies have been made of garbage and rubbish as fuel, based on proximate or ultimate analyses, and it has been found that the matter of obtaining samples in order to produce a fair average is not an easy one. This, on account of the great variation of the material, even throughout the same truck load of garbage or rubbish and, of course, seasonal variations of garbage are evident, also rainy weather greatly influences the moisture content in the collection.

Probably the most comprehensive study of garbage and rubbish ever made in this country was by the late Major I. S. Osborn, for the District of Columbia in 1914 and 1915. The staff of the U. S. Department of Agriculture, Bureau of Soils, the Department of the Interior, Bureau of Mines, cooperated in this study, making chemical analyses and determinations of moisture, combustible, ash, and Btu value of both garbage and rubbish, and proximate analyses of rubbish alone. The results of these analyses are given in Table 1.

The incinerator designer must meet contract guarantees, the most important of which is the guarantee of an odorless chimney which means, primarily, sufficient temperature in the combustion chamber. The designer in predicting combustion-chamber temperatures based on the fuel he is to handle must realize the uncertainty of anything approaching a uniform fuel, in moisture, combustible, ash, and heat values. The usual method today in taking bids, is to require the bidder to make guarantees based on specified mixtures of garbage and rubbish having a certain specified moisture, combustible, ash, and heat content.

Furnace Temperatures and Auxiliary Fuel Required

It may be of interest to follow through the development of a typical heat-balance formula and show its application to some practical problems. It is recognized that there are certain short cuts and approximations, but the following method has proved sufficiently accurate for general purposes. The nomenclature used in the method for calculating the approximate temperature in the combustion chamber, and the amount of auxiliary fuel required in burning mixed refuse is as follows:

T = temperature in combustion chamber, F
t_a = temperature of air supplied for combustion, F
K = net weight of bone-dry combustible material in refuse as fired, lb
C_k = heat value of bone-dry combustible, Btu per lb
K_c = weight of auxiliary fuel, lb per lb of refuse fired
C_c = heat value of auxiliary fuel, Btu per lb
R = net weight of residue (noncombustible and ash), lb per lb of refuse as fired
W = weight of moisture in refuse, lb per lb of refuse as fired
A = weight of air required for combustion, lb per lb of refuse as fired; this weight must include air for auxiliary fuel, if any
F = weight of dry flue gas, lb per lb of refuse as fired
H_1 = heat required for moisture in refuse

H_2 = heat required for raising dry flue gases from t_a to T
H_3 = heat losses due to radiation, unconsumed, humidity in air, incomplete combustion, hydrogen in fuel, clinkering, and unaccountable
60 F = assumed temperature of room air and refuse
0.25 = specific heat of dry flue gas, Btu per lb per deg F
0.5 = specific heat of water vapor, Btu per lb per deg F

Then for all practical purposes, $H_1 + H_2 + H_3$ = total heat in the fuel. The formulas for H_1, H_2, and H_3 are as follows:

Heat required for moisture in refuse is $W\ (212 - 60) + 970.4W + 0.5W\ (T - 212) = 152W + 970.4W - 106W + 0.5TW$, or

$$H_1 = 1016.4W + 0.5TW \qquad [1]$$

Heat required for raising dry flue gases from t_a to T deg is $0.25\ F\ (T - t_a)$, where $F = A + K + K_c$ (approximately, neglecting ash and moisture in K_c). Then $H_2 = 0.25\ (A + K + K_c)\ (T - t_a)$ or

$$H_2 = 0.25T\ (A + K + K_c) - 0.25t_a\ (A + K + K_c) \qquad [2]$$

Losses due to radiation, unconsumed, humidity in air, incomplete combustion, hydrogen in fuel, clinkering, and unaccountable is assumed to be

$$H_3 = 0.2\ (KC_k + K_c\ C_c) \qquad [3]$$

The sum of H_1, H_2, and H_3 is the total heat in the fuel and is equal to $KC_k + K_cC_c$ or $1016.4W + 0.5TW + 0.25T\ (A + K + K_c) - 0.25t_a\ (A + K + K_c) + 0.2\ (KC_k + K_cC_c) = KC_k + K_cC_c$. Reducing

$$0.25T\ (A + K + K_c) + 0.5TW = 0.8\ (KC_k + K_cC_c) + 0.25t_a\ (A + K + K_c) - 1016.4W$$

or

$$T = \frac{0.8\ (KC_k + K_cC_c) + 0.25t_a\ (A + K + K_c) - 1016.4W}{0.25\ (A + K + K_c) + 0.5W} \qquad [4]$$

As an example of how these formulas can be applied, the au-

TABLE 1 ANALYSIS OF GARBAGE AND RUBBISH

Average analysis of garbage as collected:	
Moisture, per cent	72.0
Combustible, per cent	24.4
Ash, per cent	3.6
Heat value on a wet basis, Btu per lb	2,450
Heat value on a dry basis, Btu per lb	8,775
Heat value on a net dry combustible basis, Btu per lb	10,100
Variations in garbage analysis:	
Highest moisture, per cent	85.05
Lowest moisture, per cent	63.59
Highest combustible, per cent	32.50
Lowest combustible, per cent	12.64
Highest ash, per cent	6.72
Lowest ash, per cent	2.01
Highest heat value on dry basis, Btu per lb, average	10,521
Lowest heat value on dry basis, Btu per lb, average	7,021
Average analysis of rubbish as collected:	
Moisture, per cent	7.50
Combustible, per cent	72.50
Ash and noncombustible, per cent	20.00
Heat value on a dry basis, Btu per lb	5,500
Heat value on a wet basis, Btu per lb, resolved	5,950
Heat value on a net dry combustible basis, Btu per lb, resolved	7,600
Proximate average analysis of garbage:	
Moisture, per cent	72.0
Volatile combustible, per cent	21.0
Fixed carbon, per cent	3.4
Ash and noncombustible, per cent	3.6
Proximate average analysis of rubbish:	
Moisture, per cent	7.5
Volatile combustible, per cent	59.5
Fixed carbon, per cent	13.0
Ash and noncombustible,	20.0

Volatiles for all practical purposes can be considered as methane, CH_4

TABLE 2 GARBAGE SPECIFICATIONS USED IN AUTHOR'S EXAMPLES

Assumed:
Mix to be burned is 65 per cent garbage and 35 per cent rubbish, by weight.
Garbage is 73 per cent moisture, 17 per cent net combustible, and 10 per cent ash and noncombustible.
Rubbish is 10 per cent moisture, 70 per cent net combustible, and 20 per cent ash and noncombustible.

Make-up of mix when fired:	
Water from garbage (0.65 × 0.73 = 0.475), per cent	47.5
Water from rubbish (0.35 × 0.10 = 0.035), per cent	3.5
Total water in mix as fired, per cent	51.0
Net combustible from garbage (0.65 × 0.17 = 0.11), per cent	11.0
Net combustible from rubbish (0.35 × 0.70 = 0.245), per cent	24.5
Total net combustible in mix as fired, per cent	35.5
Ash and noncombustible from garbage (0.65 × 0.10 = 0.065), per cent	6.5
Ash and noncombustible from rubbish (0.35 × 0.20 = 0.07), per cent	7.0
Total ash and noncombustible in mix as fired, per cent	13.5
Summary of mix as fired:	
Water in mix, per cent	51.0
Net combustible in mix, per cent	35.5
Ash and noncombustible in mix, per cent	13.5
Total	100.0
Heat value of mix as fired (8000 × 0.355), Btu per lb	2840

Air required to burn the mix:
The approximate theoretical air for chemical requirements for fuel of this character may be assumed as in the same proportion to air required for coal with a heat value of 14,500 Btu, as the heat value of the mix is to 14,500 Btu, or

$$\frac{\text{Air per lb of mix}}{\text{Air per lb of 14,500-Btu coal}} = \frac{\text{Heat value of mix}}{\text{14,500 Btu of coal}}$$

thor has selected a problem, using as a basis the specifications given in Table 2, which were recently given by one city.

Experience shows that it is possible to operate an incinerator with less than 100 per cent excess air, and that 50 per cent excess is a fair average with refuse of the character under consideration.

Therefore, the approximate theoretical air required to burn the mix as fired is (2840/14,500) × 12 = 2.35 lb, or 3.53 lb at 50 per cent excess, and 4.70 lb at 100 per cent excess. By substituting values in Equation [4] for T using 50 per cent excess air and no auxiliary fuel, with preheated air at 400 F

$$T = \frac{0.8\ (8000 \times 0.355 + 0) + 0.25\ [400\ (3.53 + 0.355)] - (1016.4 \times .51)}{0.25\ (3.53 + 0.355) + (0.5 \times 0.51)}$$

or $T = 1740$ F.

By substituting values in Equation [4] for T using 100 per cent excess air and no auxiliary fuel with preheated air at 400 F

$$T = \frac{0.8\ (8000 \times 0.355 + 0) + 0.25\ [400\ (4.70 + 0.355)] - (1016.4 \times .51)}{0.25\ (4.70 + 0.355) + (0.5 \times 0.51)}$$

or $T = 1485$ F.

It would be quite proper to guarantee an average combustion-chamber temperature of 1450 F in the light of these calculations.

To determine how much coal of 14,000-Btu value will be necessary to burn wet garbage, with no rubbish and no preheated air, and air for combustion being delivered at room temperature of 60 F. Assume that the mix to be burned is garbage and coal (amount of coal to be determined); garbage is 73 per cent moisture, 17 per cent net combustible, and 10 per cent ash and noncombustible; heat value of net combustible in garbage is 8000 Btu per lb; heat value of coal is 14,000 Btu per lb as fired, neglecting moisture and ash in coal; temperature required in combustion chamber is 1500 F; and the air required to burn coal is 18 lb per lb of coal as fired.

Then the theoretical air required to burn garbage is (8000 × 0.17/14,500) × 12 = 1.125 lb air per lb garbage. At 50 per cent excess 1.687 lb air is required. The total air for coal + garbage = $(K_c \times 18) + 1.687$.

Substituting in Equation [4]

$$1500 = \frac{0.8\,(8000 \times 0.17 + K_c \times 14{,}000) + 0.25 \times 60\,(K_c \times 18 + 1.687 + 0.17 + K_c) - 1016.4 \times 0.73}{0.25\,(K_c \times 18 + 1.687 + 0.17 + K_c) + 0.5 \times 0.73}$$

$$= \frac{1088 + 11{,}200K_c + 270K_c + 27.8 + 15K_c - 742}{4.5K_c + 0.464 + 25K_c + 0.365} = \frac{373.8 + 11{,}485K_c}{4.75K_c + 0.829}$$

Hence

$7125K_c + 1243 = 373.8 + 11{,}485K_c$ and $K_c = 0.20$ lb of coal per lb of garbage.

Thus, 400 lb of coal will be required to burn each ton of garbage without preheated air and maintain a combustion-chamber temperature of 1500 F.

Value of Preheated Air. Assuming the same factors for garbage and coal as just given, and by employing preheated air at 400 F, and substituting in Equation [4]

$$1500 = \frac{0.8\,(8000 \times 0.17 + K_c \times 14{,}000) + 0.25 \times 400\,(K_c \times 18 + 1.687 + 0.17 + K_c) - 1016.4 \times 0.73}{0.25\,(K_c \times 18 + 1.687 + 0.17 + K_c) + 0.5 \times 0.73}$$

$$= \frac{1088 + 11{,}200K_c + 1800K_c + 185.7 + 100K_c - 742}{4.5K_c + 0.464 + 0.25K_c + 0.365} = \frac{531.7 + 13{,}100K_c}{4.75K_c + 0.829}$$

Hence

$$7125K_c + 1243 = 531.7 + 13{,}100K_c$$

and

$$K_c = 0.119 \text{ lb of coal per lb of garbage}$$

Thus, 238 lb of coal will be required to burn each ton of garbage, and maintain a combustion-chamber temperature of 1500 F, using preheated air at 400 F.

It is evident that the use of a preheater in this rather extreme case, burning wet garbage with no rubbish, saves the difference between 400 lb and 238 lb, or 162 lb of coal per ton of garbage burned. In other words, this 162 lb of coal is the value of the recovered heat per ton of garbage burned, made possible through the employment of a preheater and heating the air to 400 F not alone as required for combustion of the garbage, but also for the combustion of the coal.

With a preheater there is required 1.687 lb of air per lb of garbage, and $18 \times 0.119 = 2.142$ lb of air for 0.119 lb of coal, or total air per pound of garbage = 3.829 lb. In other words, there is returned to furnace in 3.829 lb of air preheated from 60 F to 400 F, using 0.25 as specific heat of air, $3.829 \times 340 \times 0.25 =$ 325 Btu per lb of garbage, or 650,000 Btu per ton of garbage returned to furnace. This, you will note, is equivalent only to 46.5 lb of 14,000 Btu coal in direct heat value, whereas the actual coal saving indicated is 162 lb per ton of garbage burned. In explanation of this difference it can be readily realized that approximately 70 per cent of the heat liberated in burning the coal under the conditions obtaining goes to raising the dry gases of its own production to 1500 F, and to clinkering and other losses, leaving only 30 per cent for effective work. This is a startling argument in favor of preheated air.

Experience with the heat-balance formulas given by the author has shown that actual operation checks satisfactorily for all practical purposes with the predictions made. The experienced incinerator engineer will use any theoretical formulas that he may develop with judgment and a margin of safety, realizing that his margin of safety may sometimes be the means of his salvation in meeting the contract guarantees.

From what has preceded, the figures disclosed may leave the reader with the impression that it is not possible to burn wet garbage in an incinerator without the aid of auxiliary fuel, or even with the use of preheated air to assist in the burning; however, it will be recalled that the preceding figures have all been based on a heat balance in which the waste gases are discharged at high temperature, reaching the chimney at approximately 1000 F under practical operating conditions. It is possible, however, to destroy wet garbage without the use of any heating values other than those inherent in the combustible material in the garbage itself, and in so doing to maintain combustion-chamber temperatures in excess of 1800 F, which are well above the point required to eliminate any objectionable odors. However, to accomplish this result, and in order to effect combustion of the garbage, it is necessary to condition same by predrying the wet garbage.

The method employed has been completely demonstrated on a commercial scale by employing a rotary garbage drier reducing the wet garbage to 35 or 40 per cent moisture content, and then returning this dried garbage to the dryer furnace, and employing the same as fuel for further drying operations, using the necessary flue gases for this purpose. Not alone in theory, but also in practice, the heat produced by the burning of the dried garbage is considerably in excess of the requirements for drying—so much so that it is necessary to provide a bypass to permit passing the excess gases over and above what are required to do the drying, or the excess garbage fuel may be burned in separate furnaces. A parallel-flow drier is employed for the drying for the reason that the hottest gases come directly in contact with the wettest garbage; and, as the garbage, in its passage toward the discharge end, becomes less moist, the gases in like travel are being reduced in temperature which insures against scorching.

Because of the results thus obtained in these operations in successfully destroying garbage, patents were obtained covering this method; however, to date, no municipality has this method in continuous operation.

In the author's opinion, before many years developments and installations will have been made, employing mechanical charging and stoking of incinerator furnaces, with mechanical aid for ash handling and that these or some such developments will come from the activities of some of those cities now spending so much time in the study of incineration.

Prevailing practice, as related to specifications, requires that bidders make a statement to the effect that they have designed and built incinerators of the type bid upon, which have been in successful operation for at least two years, and are still in satisfactory operation at the time of making the bid. Should this practice be continued in future specifications, it would seem that developments based upon experimental work must come from those cities interested in mechanically operated plants, as any new developments presented by incinerator engineers would probably not be considered, because of the qualifications just mentioned.

Temperature and Combustion Rates in Fuel Beds

By MARTIN A. MAYERS,[1] PITTSBURGH, PA.

Since the classical investigations of Kreisinger, Augustine, and Ovitz (1),[2] on the reactions and temperatures in a fuel bed, there has been increasing interest in this subject, and measurements similar to those reported in their paper have been repeated by several others (2, 3, 4, 5) with different types of fuels. In addition, Nicholls (6) and Nicholls and Eilers (7) have developed recently an experimental method for determining the characteristics of fuels in underfeed combustion. In spite of the interest shown in this subject, there have been no theoretical investigations of the problem, with the result that the experimental results remain, to a large extent, uncoordinated. It is the purpose of this paper to supply a first step toward meeting this deficiency.

THE nomenclature used in this paper is as follows:

c_p = specific heat of air and combustion gases, Btu per lb per deg F
h_1 = heat of combustion of reaction $C + O_2 \rightarrow CO_2$, Btu per lb O_2
h_2 = heat of reaction $C + CO_2 \rightarrow 2\,CO$, Btu per lb CO_2
k = coefficient of thermal conductivity of bed, Btu per ft per hr per deg F
l = depth of fuel bed, ft
p_1 = concentration of oxygen in combustion gases, fraction
p_2 = concentration of carbon dioxide in combustion gases, fraction
p_3 = concentration of carbon monoxide in combustion gases, fraction
x = distance from grates, ft
x_1 = distance of plane of ignition from grates, ft
G = rate of gas flow through fuel bed, lb per sq ft per hr
M = stoichiometric factor = 0.414
P_1 = concentration of oxygen in entering air, fraction
T = temperature elevation of fuel bed above surroundings, deg F
T_1 = temperature elevation of the fuel bed above surroundings at plane of ignition, deg F
T_i = ignition temperature of fuel, deg F
T_a = temperature elevation of air and combustion gases, deg F
U = rate of fuel flow and of combustion in the steady state, lb per sq ft per hr
U_i = rate of advance of plane of ignition (and fuel feed in unrestricted ignition), lb per sq ft per hr
α = coefficient of heat transfer between solids of fuel bed and combustion gases, Btu per cu ft per hr per deg F
β = coefficient of heat transfer from bottom of fuel bed to surroundings, Btu per sq ft per hr per deg F
γ = coefficient of heat transfer from top of fuel bed to surroundings, Btu per sq ft per hr per deg F
μ_1 = specific rate of the reaction $C + O_2 \rightarrow CO_2$, lb per cu ft per hr
μ_2 = specific rate of the reaction $C + CO_2 \rightarrow 2\,CO$, lb per cu ft per hr
ρ = specific heat of the fuel, Btu per lb per deg F

The General Equations

The fundamental concept on which the following considerations are based is that heat flows through a fuel bed in two ways: First, by convection by the air supplied for combustion and the resultant gases; and second, by a process obeying the laws of metallic conduction. The latter process is not limited as to mechanism, although it probably occurs through radiation between adjacent particles. It is sufficient for the present purpose that a property equivalent to thermal conductivity exists for the fuel bed as a whole and that it be measurable (8, 9, 10). This process is—solely in the case of underfeed fuel beds, and partially in overfeed fuel beds—responsible for heating the incoming green fuel up to its ignition temperature.

For the purpose of this discussion, use will be made of a simplified fuel bed such as shown in Fig. 1. The bed is considered to be a continuous solid, of a porous nature such that air can be blown through it. In effect, this focuses attention on the fuel bed as a whole, rather than on the individual pieces of which it is composed. The x-direction is taken as the direction of air (or gas) flow through the bed, usually vertically upward, and the bed extends from zero to l which need not be constant. Variation of the properties of the bed in the x-direction only will be considered; for the present, variations in the planes normal to the x-direction will be neglected. If there is a flow of fuel through the bed, it will be considered positive if in the positive x-direction. Ignition is supposed to take place at some plane designated by $x = x_1$, where x_1 may have any value from zero to l, and combustion takes place from there to the end of the bed, $x = l$. The differential equation for the temperature of the bed may then be stated as

$$\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) - \frac{\partial}{\partial x}(\rho U T) - \alpha\,(T - T_a) = \frac{\rho}{d}\frac{\partial T}{\partial t} + X(T) - \phi(x, x_1) \quad \ldots\ldots [1]$$

[1] Member of Staff, Coal Research Laboratory, Carnegie Institute of Technology. Jun. A.S.M.E. Mr. Mayers was graduated from Sheffield Scientific School, Yale, in 1927 with degree of B.S. From 1927 until January, 1929, he was employed by the Brooklyn Edison Company as a junior engineer in the test bureau, being stationed most of that time at Hudson Avenue generating station. He then worked for a short period as engineer for the Prat-Daniel Corporation, now of Port Chester, N. Y., erecting and servicing air preheaters and draft-producing equipment. During the scholastic year 1929–1930 he returned to Yale to study for the degree of M.S. in mechanical engineering. On the completion of this course he was employed for six months by Sargent & Lundy, Inc., as assistant research engineer, resigning to take up his present work in December, 1930. In this position he has engaged in fundamental research on the combustion of solid fuels and is the author of several contributions to the technical press on this subject.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

Contributed by the Fuels and Steam Power Division, and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

where T represents the temperature of the fuel; T_a that of the air or gas stream; k the thermal conductivity of the bed; ρ the heat capacity of the fuel; U its rate of flow through the bed; d its bulk specific gravity; and α represents the heat-transfer coefficient between fuel and the air stream—it refers to a unit of volume of the bed and contains the surface effective in heat transfer as a factor. The term $X(T)$ represents the heat absorbed in endothermic reactions such as coking or cracking, while ϕ represents the heat liberated by combustion and is given by

$$\phi(x, x_1) = \begin{cases} 0, \text{ when } 0 \leqslant x \leqslant x_1 \\ \mu_1 h_1 p_1 (x, x_1) - \mu_2 h_2 p_2 (x, x_1), \text{ when } x_1 \leqslant x \leqslant l \end{cases} \quad [2]$$

where μ_1 and μ_2 represent the rates of the reactions (A), $C + O_2 \rightarrow CO_2$ and (B), $C + CO_2 \rightarrow 2\,CO$, respectively, at unit concentration of the reacting gases—they also refer to unit volume of the bed just as does α; h_1 and h_2 are the quantities of heat liberated or absorbed in the reactions (A) and (B) referred to unit weight of the reacting gases; and p_1 and p_2 represent the fractional concentrations of O_2 and CO_2, respectively.

In Equation [1] the first term represents the gain of heat by an element of volume due to conduction; the second represents the loss to an element due to the heat carried away by the fuel flowing through it; the third represents the loss due to the transfer of heat from the solid fuel to the air or gas stream; and the fourth represents the heat absorbed in local rise in temperature. Thus the left-hand side of Equation [1] represents the net gain of heat in an element of volume due to transport processes, while the right-hand side represents the net absorption of heat by reaction and by increase of temperature, so that the equation is simply a heat balance.

The temperature of the air stream satisfies the equation

$$Gc_p \frac{\partial T_a}{\partial x} - \alpha(T - T_a) = 0 \ldots\ldots\ldots\ldots\ [3]$$

where G represents the rate of air or gas flow, and c_p is the specific heat of the gas. This equation states that the heat absorbed in raising the temperature of the gas passing through an element of volume is equal to the heat transferred to the gas from the fuel.

The concentrations of the various constituents of the gas stream satisfy the set of equations

$$\left.\begin{aligned} G\frac{\partial p_1}{\partial x} + \mu_1 p_1 &= 0 \\ G\frac{\partial p_2}{\partial x} + \mu_2 p_2 &= \mu_1 p_1 \\ G\frac{\partial p_3}{\partial x} &= 2\,\mu_2 p_2 \end{aligned}\right\} \text{ when } x_1 < x \leqslant l \ldots\ldots [4]$$

where p_3 represents the concentration of CO. The significance of these equations is exemplified by the second, which states that the rate of increase in quantity of CO_2 in the gas stream, given by the term $G(\partial p_2/\partial x)$, plus the rate of loss by reaction to form CO, given by $\mu_2 p_2$, is equal to the rate of formation of CO_2 from O_2, given by the term $\mu_1 p_1$.

It may be noted in passing that in the three-dimensional case the only changes that would appear in these equations are that the first term in Equation [1] would be replaced by the appropriate Laplacian, while the first derivatives with respect to the space coördinate x in Equations [1], [3], and [4] would be replaced by the divergences of the appropriate quantities.

Equations [1] to [4], inclusive, with suitable boundary conditions would be sufficient to determine a general solution for the one-dimensional case, but the mathematical difficulties are great. It is advisable to limit the problem further to secure simplicity in the mathematical treatment.

The Steady State With Pure Underfeed Burning

In the first place it is advantageous to neglect changes in the values of the coefficients in the differential equations due to ash or to changes in position in the bed. In effect, the solid representing the fuel bed will be required to be uniform and isotropic, as well as continuous, which means simply that for α, ρ, k, μ_1, and μ_2 suitable average values must be used. In addition X will be assumed to vanish, and U and G will be assumed constant. Although G actually increases by about 10 per cent during the passage of the gas through the bed, this change can be neglected without vitiating the analysis. The rate of fuel flow U decreases in a real fuel bed by an amount equal to the product of the fraction of the combustible in the fuel and the difference between the initial value of U and the combustion rate, but since its effect on the temperature is important only close to the plane of ignition where it has departed very slightly from its original value, this variation may also be neglected.

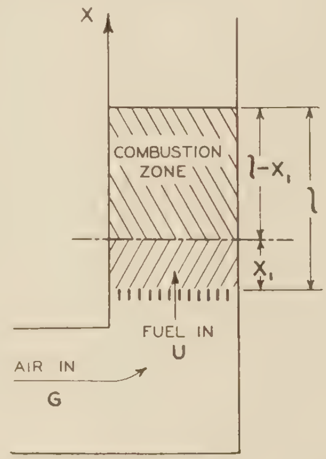


Fig. 1 Representation of Simplified Fuel Bed

The second limitation is on the mechanical system. Let the fuel be charged at the bottom of the bed at the same rate as that at which it is burned. Then the fuel-bed height l will remain constant and a steady state will be reached in which the temperatures and concentrations at any point in the bed do not change with time. The fuel-feeding mechanism is restricted in that it must not interfere with the admission of air over the entire grate surface, so that the combustion proceeds by pure underfeed action, as this term is defined by Nicholls (6, 7). The restriction to the steady state makes it possible to eliminate the term in $\partial T/\partial t$ in Equation [1], and to use ordinary, instead of partial, derivatives throughout, thus markedly simplifying the analysis. Thus, the differential equations become

$$\frac{d^2 T}{dx^2} - \frac{\rho U}{k}\frac{dT}{dx} - \frac{\alpha}{k}(T - T_a) = \begin{cases} 0, \text{ when } 0 \leqslant x \leqslant x_1 \\ -\frac{1}{k}[\mu_1 h_1 p_1 - \mu_2 h_2 p_2], \text{ when } x_1 \leqslant x \leqslant l \end{cases} \ldots [5]$$

$$\frac{dT_a}{dx} - \frac{\alpha}{Gc_p}(T - T_a) = 0, \text{ when } 0 \leqslant x \leqslant l \ldots\ldots\ [6]$$

$$\left.\begin{aligned}&\frac{dp_1}{dx}+\frac{\mu_1}{G}p_1=0\\&\frac{dp_2}{dx}+\frac{\mu_2}{G}p_2=\frac{\mu_1}{G}p_1\\&\frac{dp_3}{dx}=2\frac{\mu_2}{G}p_2\end{aligned}\right\}\text{ when } x_1\leqslant x\leqslant l\ldots\ldots[7]$$

In setting up the boundary conditions, the ambient temperature may be taken as zero, and the calculated values of T will then be the elevations in temperature above that of the surroundings. The fuel bed loses heat from both its top and bottom surfaces by radiation to the surroundings at rates that will be assumed proportional to the respective temperature elevations. This assumption is not strictly correct since the heat transfer by radiation varies as the difference of the fourth powers of the absolute temperatures, but this error may be compensated by choosing the heat-transfer coefficient appropriate to the temperature (11). Then the boundary conditions on T become

$$\left.\begin{aligned}&\frac{dT}{dx}-\frac{\beta+\rho U}{k}T=0,\quad \text{at } x=0\\&\frac{dT}{dx}+\frac{\gamma}{k}T=0,\quad \text{at } x=l\end{aligned}\right\}\ldots\ldots[8]$$

where β and γ are the equivalent radiation heat-transfer coefficients at the bottom and the top of the bed, respectively. The quantity $\rho U/k$ is included as a coefficient in the first of Equations [8] because it is necessary to provide sufficient heat at the bottom of the bed to raise the temperature of the incoming fresh fuel from that of the surroundings to that of the bed at $x = 0$.

The temperature of the air entering the fuel bed is, of course, that of the surroundings, so that the initial condition on T_a is

$$T_a = 0\ldots\ldots\ldots\ldots[9]$$

at $x = 0$. The concentration of oxygen in the entering air has its initial value P_1, which is maintained until combustion starts at $x = x_1$, while over the same range the concentrations of carbon dioxide and carbon monoxide remain zero, so that

$$\left.\begin{aligned}&p_1=P_1,\quad \text{when } x\leqslant x_1\\&p_2=p_3=0,\ \text{when } x\leqslant x_1\end{aligned}\right\}\ldots\ldots[10]$$

In the steady state the rate of fuel flow U is equal to the rate of combustion, so it may be calculated from the gas analysis at the top of the bed, giving

$$U = M\,G\,[p_2(l)+p_3(l)]\ldots\ldots\ldots\ldots[11]$$

where M is a stoichiometric factor. It may be noted that, in the steady state, overfeed combustion would be represented by changing the sign of U.

Solution of the Differential Equations

Equations [7] with the initial conditions of Equations [10] can be solved immediately, giving

$$p_1=\left\{\begin{aligned}&P_1,\ \text{when } x\leqslant x_1\\&P_1e^{-\frac{\mu_1}{G}(x-x_1)},\ \text{when } x_1\leqslant x\leqslant l\end{aligned}\right\}\ldots\ldots[12]$$

$$p_2=\left\{\begin{aligned}&0,\ \text{when } x\leqslant x_1\\&\frac{P_1}{1-\frac{\mu_2}{\mu_1}}\left[e^{-\frac{\mu_2}{G}(x-x_1)}-e^{-\frac{\mu_1}{G}(x-x_1)}\right]\ \text{when } x_1\leqslant x\leqslant l\end{aligned}\right\}\ [13]$$

$$p_3=\left\{\begin{aligned}&0,\ \text{when } x\leqslant x_1\\&2P_1\left[1-\frac{e^{-\frac{\mu_2}{G}(x-x_1)}-\frac{\mu_2}{\mu_1}e^{-\frac{\mu_1}{G}(x-x_1)}}{1-\frac{\mu_2}{\mu_1}}\right],\\&\qquad\text{when } x_1\leqslant x\leqslant l\end{aligned}\right\}\ldots[14]$$

Using these values of p, the combustion rate U may be calculated from Equation [11], giving

$$U = GP_1M\left[\left(1\quad e^{-\frac{\mu_1}{G}(l-x_1)}\right)+\left(1-\frac{e^{-\frac{\mu_2}{G}(l-x_1)}-\frac{\mu_2}{\mu_1}e^{-\frac{\mu_1}{G}(l-x_1)}}{1-\frac{\mu_2}{\mu_1}}\right)\right]\ldots[15]$$

Equations [12], [13], and [14] are essentially the same as those reported recently by Furnas (12) except that the K values used by him are replaced here by μ/G.

In order to determine T it is necessary to eliminate T_a between Equations [5] and [6], giving

$$\frac{d^3T}{dx^3}-2b\frac{d^2T}{dx^2}-(c^2-b^2)\frac{dT}{dx}$$
$$=\left\{\begin{aligned}&0,\ \text{when } 0\leqslant x\leqslant x_1\\&-\frac{\mu_1h_1}{k}\left(\frac{\alpha}{Gc_p}p_1+\frac{dp_1}{dx}\right)+\frac{\mu_2h_2}{k}\left(\frac{\alpha}{Gc_p}p_2+\frac{dp_2}{dx}\right),\\&\qquad\text{when } x_1\leqslant x\leqslant l\end{aligned}\right\}\ldots[16]$$

where

$$b=\frac{1}{2}\left(\frac{\rho U}{k}-\frac{\alpha}{Gc_p}\right)=\frac{1}{2}\sqrt{\frac{\alpha}{k}}\left(\frac{\rho U}{\sqrt{\alpha k}}-\frac{\sqrt{\alpha k}}{Gc_p}\right)\ldots[17]$$

and

$$c^2=\frac{\alpha}{k}\left(1+\frac{\rho U}{Gc_p}\right)+b^2=\frac{\alpha}{k}\left[1+\frac{1}{4}\left(\frac{\rho U}{\sqrt{\alpha k}}+\frac{\sqrt{\alpha k}}{Gc_p}\right)^2\right].[18]$$

while the boundary condition expressed by Equation [9] is replaced by

$$\frac{d^2T}{dx^2}-\frac{\rho U}{k}\frac{dT}{dx}-\frac{\alpha}{k}T=0\ldots\ldots\ldots[19]$$

at $x = 0$. A solution of the system defined by Equations [16], [19], and [8] could be obtained by the use of Green's function in the form of its bilinear expansion, but the resulting series converges very slowly because of the magnitude of c. Hence, elementary methods give a more satisfactory form of solution. The appropriate forms for the solution are

$$T = e^{bx}(A\cosh cx + B\sinh cx)+C\ldots\ldots[20a]$$

when $0\leqslant x\leqslant x_1$

$$T = e^{bx}(A\cosh cx+B\sinh cx)+e^{b(x-x_1)}(D\cosh c(x-x_1)$$
$$+E\sinh c(x-x_1))+F+\psi(x,x_1)\ldots[20b]$$

when $x_1\leqslant x\leqslant l$ and where ψ is the particular solution required for the right-hand side of Equations [16] when the values of p_1 and p_2 are substituted from Equations [12] and [13], and is given by

$$\psi = -\frac{P_1 h_1 \left(\frac{\alpha}{c_p} - \mu_1\right) e^{-\frac{\mu_1}{G}(x-x_1)}}{k\left[c^2 - \left(b + \frac{\mu_1}{G}\right)^2\right]} + \frac{P_1 h_2}{k\left(1 - \frac{\mu_2}{\mu_1}\right)} \left\{\frac{\left(\frac{\alpha}{c_p} - \mu_2\right) e^{-\frac{\mu_2}{G}(x-x_1)}}{c^2 - \left(b + \frac{\mu_2}{G}\right)^2} - \frac{\frac{\mu_2}{\mu_1}\left(\frac{\alpha}{c_p} - \mu_1\right) e^{-\frac{\mu_1}{G}(x-x_1)}}{c^2 - \left(b + \frac{\mu_1}{G}\right)^2}\right\} \quad \text{[20c]}$$

The six arbitrary constants A to F, inclusive, are determined by a system of six linear equations; three given by the boundary conditions of Equations [19] and [8]; two more by the obvious requirements that the temperature and its first derivative be continuous at $x = x_1$; and the last, by the equation, obtained by eliminating T, dT/dx, and T_a between the two expressions of Equation [5] evaluated at $x = x_1$

$$\left.\frac{d^2T}{dx^2}\right|^{x_1+0} - \left.\frac{d^2T}{dx^2}\right|^{x_1-0} = -\frac{1}{k}\left[\mu_1 h_1 p_1(x_1) - \mu_2 h_2 p_2(x_1)\right] \quad \text{[21]}$$

These equations are given in the Appendix.

The complete expressions for the temperature given in the Appendix are rather complicated, but they may be considerably simplified by the application of the approximation, correct to within 0.3 per cent when u is greater than 3, that

$$\cosh u = \sinh u = \frac{1}{2} e^u$$

Because of the great magnitude of c as defined by Equation [18] cl is greater than 3 for all practical fuel beds. With this approximation, T for the region where $x > x_1$ is given by

$$T = P_1 \left\{ h_1 \left[\frac{1 - e^{-(c-b)(x-x_1)}}{c_p + \frac{U}{G}\rho} - \frac{e^{-\frac{\mu_1}{G}(x-x_1)} - e^{-(c-b)(x-x_1)}}{\frac{c_p}{1 - \mu_1/\frac{\alpha}{c_v}} + \frac{U}{G}\rho + \frac{\mu_1 k}{G^2}} \right] \right.$$

$$- h_2 \left[\frac{1 - e^{-(c-b)(x-x_1)}}{c_p + \frac{U}{G}\rho} - \frac{1}{1 - \frac{\mu_2}{\mu_1}} \left(\frac{e^{-\frac{\mu_2}{G}(x-x_1)} - e^{-(c-b)(x-x_1)}}{\frac{c_p}{1 - \mu_2/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_2 k}{G^2}} \right.\right.$$

$$\left.\left.\left. - \frac{\mu_2}{\mu_1} \frac{e^{-\frac{\mu_1}{G}(x-x_1)} - e^{-(c-b)(x-x_1)}}{\frac{c_p}{1 - \mu_1/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_1 k}{G^2}} \right) \right] \right\} \left[1 - \frac{\frac{\gamma}{k} e^{-(c+b)(l-x)}}{c + b + \frac{\gamma}{k}} \right]$$

$$+ P_1 \frac{\mu_1 \left(c + b + \frac{\alpha}{Gc_p}\right) e^{-(c-b)(x-x_1)}}{2kc(c+b)\left(c + b + \frac{\mu_1}{G}\right)} \left(h_1 - \frac{\frac{\mu_2}{G} h_2}{c + b + \frac{\mu_2}{G}} \right) \quad \text{[22]}$$

Below the plane of ignition, where $x < x_1$

$$T = T_1 e^{-(c+b)(x_1-x)} \quad \text{[23]}$$

where cx_1 is greater than 3. In this expression, T_1 is the temperature at the plane of ignition, and is given by

$$T_1 = P_1 \left[\frac{\mu_1 \left(c + b + \frac{\alpha}{Gc_p}\right)\left(h_1 - \frac{\frac{\mu_2}{G} h_2}{c + b + \frac{\mu_2}{G}}\right)}{2kc(c+b)\left(c + b + \frac{\mu_1}{G}\right)} \right.$$

$$- \frac{h_1 \frac{\gamma}{k} e^{-(c+b)(l-x_1)}}{c + b + \frac{\gamma}{k}} \cdot \left(\frac{1}{c_p + \frac{U}{G}\rho} \right.$$

$$\left.\left. - \frac{\left(1 - \frac{\mu_1}{G} \Big/ \frac{\gamma}{k}\right) e^{-\frac{\mu_1}{G}(l-x_1)}}{\frac{c_p}{1 - \mu_1/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_1 k}{G^2}} \right) \right] \quad \text{[24]}$$

Restricted and Unrestricted Ignition

The temperature at the plane of ignition T_1, could now be calculated from Equation [24] for various assumed values of $(l - x_1)$ and G, and the assumption of an ignition temperature for the fuel would fix the relation between the first two variables. It is found, however, that this holds only above a certain minimum value of G; below this value, T_1 will be greater than the ignition temperature, no matter how great $(l - x_1)$ be taken. This result evidently is equivalent to the effect found experimentally by Nicholls (6) that below some value of air-flow rate, the rate of advance of the ignition zone is greater than the rate of combustion.

In this region the definitions of restricted and unrestricted ignition, given by Nicholls, will be adopted. In combustion with unrestricted ignition, the fuel is fed at the rate of advance of the plane of ignition, so that the temperature elevation of the fuel at its inlet is zero. This condition is not practically desirable as it leads to a fuel bed of continually increasing thickness. It can, however, be calculated from the results of the previous section. Inspection of Equation [22] shows that the effect of radiation from the top surface of the fuel bed, given by the factor

$$\left[1 - \frac{\frac{\gamma}{k} e^{-(c+b)(l-x)}}{c + b + \frac{\gamma}{k}} \right]$$

extends only a short distance into the fuel bed, and is entirely negligible at $x = x_1$ for beds of practical thickness. Hence, the condition that the fuel bed must remain of constant thickness, given by Equation [15], may be abrogated, and U may be determined by the condition that

$$T_1 = T_i \quad \text{[25]}$$

where T_i is the ignition temperature of the fuel. For this case, only the first term of Equation [24] defining T_1, is significant, and Equation [25] may be put in the form

$$\frac{c_p T_i}{P_1 h_1} = \frac{\mu_1}{2\frac{\alpha}{c_p}} \frac{\left[\sqrt{1+\theta^2} + \theta\right]}{\sqrt{1+\theta^2}\left[\sqrt{1+\theta^2} + \theta - \frac{\sqrt{\alpha k}}{Gc_p}\right]} \times \frac{1}{\left[\sqrt{1+\theta^2} + \theta - \frac{\sqrt{\alpha k}}{Gc_p}\left(1 - \mu_1/\frac{\alpha}{c_p}\right)\right]} \quad \text{[26]}$$

where $\theta = \frac{1}{2}\left[\frac{\rho U}{\sqrt{\alpha k}} + \frac{\sqrt{\alpha k}}{G c_p}\right]$, so that all the terms are dimensionless.

In combustion with restricted ignition, the fuel-bed thickness is maintained constant, and the temperature of the bed at its base is above the ignition temperature, so that $x_1 = 0$ and combustion occurs throughout the height of the bed. For this condition a slightly different form of solution for the temperature T is required, as, since $x_1 = 0$, the continuity conditions of Equation [21] and the preceding paragraph need not be satisfied. The appropriate form is

$$T = e^{bx}\left[A' \cosh cx + B' \sinh cx\right] + C' + \psi(X) \ldots\ldots [27]$$

where ψ has the same value as in Equation [20c] except that x_1 vanishes. The constants A', B', and C' are determined by the three boundary conditions given in Equations [8] and [19], and the solution, abridged in the same way as that of Equation [22] is

$$T = P_1 \left\{ h_1 \left[\frac{\left(1 - \mu_1 / \frac{\alpha}{c_p}\right)\left(1 - e^{-(c-b)x}\right)}{c_p + \frac{U}{G}\rho} - \frac{e^{-\frac{\mu_1}{G}x} - e^{-(c-b)x}}{\frac{c_p}{1 - \mu_1/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_1 k}{G^2}} \right] \right.$$

$$- h_2 \left[\frac{1 - e^{-(c-b)x}}{c_p + \frac{U}{G}\rho} - \frac{1}{1 - \frac{\mu_2}{\mu_1}} \left(\frac{e^{-\frac{\mu_2}{G}x} - e^{-(c-b)x}}{\frac{c_p}{1 - \mu_2/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_2 k}{G^2}} \right. \right.$$

$$\left. \left. \left. - \frac{\frac{\mu_2}{\mu_1}\left(e^{-\frac{\mu_1}{G}x} - e^{-(c-b)x}\right)}{\frac{c_p}{1 - \mu_1/\frac{\alpha}{c_p}} + \frac{U}{G}\rho + \frac{\mu_1 k}{G^2}} \right) \right] \right\} \left[1 - \frac{\frac{\gamma}{k} e^{-(c-b)(l-x)}}{c + b + \frac{\gamma}{k}} \right]$$

$$+ P_1 \frac{\mu_1 \left[e^{-(c-b)x} - \frac{\beta}{\beta + \rho U + G c_p} \left(1 - \frac{\frac{\gamma}{k} e^{-(c+b)(l-x)}}{c + b + \frac{\gamma}{k}} \right) \right]}{k(c+b)\left(c + b + \frac{\mu_1}{G}\right)\left(c - b + \frac{\beta + \rho U}{k} \frac{\rho U + G c_p}{\beta + \rho U + G c_p}\right)}$$

$$\left[\left(\frac{\alpha}{G c_p} - \frac{\mu_1}{G} \right) h_1 - \frac{\frac{\mu_2}{G}\left(c + b + \frac{\alpha}{G c_p}\right) h_2}{c + b + \frac{\mu_2}{G}} \right] \ldots . [28]$$

Comparison of Calculated and Experimental Results

In order to calculate results from the equations presented in this paper, it is necessary to make estimates of the values of the coefficients appearing in them. These coefficients have been subjected to sporadic and partial investigation only, and in many cases even their order of magnitude is not known. What information is available concerning them is dealt with by the author in another paper (13). The values of the coefficients used are given in Table 1. They were obtained by choosing those values from the literature which gave reasonably good agreement between the temperatures observed by Nicholls (14) and those calculated according to Equation [22].

TABLE 1 VALUES OF COEFFICIENTS USED IN THE VARIOUS EQUATIONS

Fuel size	$^1/_2 \times 1$ in.	$1 \times 1^1/_2$ in.	$2 \times 2^1/_2$ in.
α, Btu per cu ft per hr per deg F.	6350	6000	5350
k, Btu per ft per hr per deg F.	1.525	2.24	3.65
W,[a] lb per cu ft per hr	26.1	15.2	8.16
μ_2/μ_1	0.267, $x < 0.5$ ft;	$\mu_2/G = 0.03$, $x > 0.5$ ft	
β, Btu per sq ft per hr per deg F.		5.	
γ, Btu per sq ft per hr per deg F.		12.50	
ρ, Btu per lb per deg F.		0.34	
c_p, Btu per lb per deg F.		0.28	

[a] W is the coefficient of $G/100$ in the expression $\mu_1/G = W\,[(G/100)^{-0.5}]$

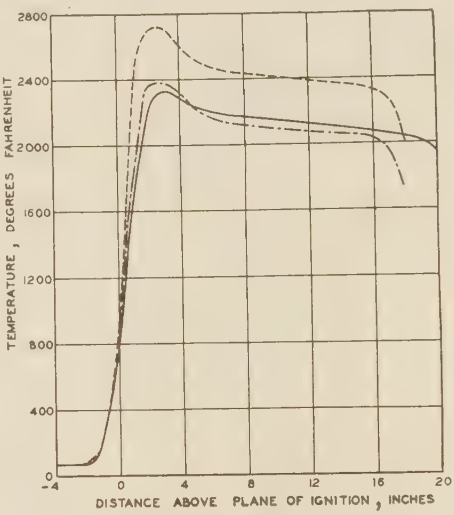

FIG. 2 TEMPERATURES IN UNDERFEED FUEL BED

(Solid curve plotted from experimental values (14). Dashed curve plotted from values calculated for unrestricted ignition. Dot-and-dash curve plotted from values calculated for restricted ignition. Air-flow rate = 160 lb per sq ft per hr, combustion rate = 25 lb per sq ft per hr, and rate of advance of ignition zone = 36.1 lb per sq ft per hr.)

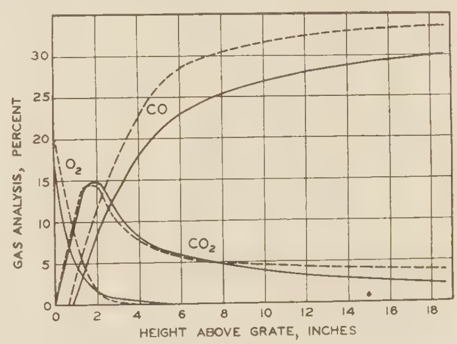

FIG. 3 GAS ANALYSIS IN A FUEL BED

(Solid curve plotted from experimental values (6, 7). Dashed curve plotted from calculated values.)

In Fig. 2, the full line shows the temperatures measured in an experimental underfeed fuel bed. The dashed line shows the temperatures calculated for the same conditions for unrestricted ignition from Equations [22] and [23] while the dot-and-dash line shows the temperatures calculated for restricted ignition from Equation [28]. In comparing the experimental and calculated curves for unrestricted ignition, the following points of difference appear:

(a) The calculated curve is from 200 F to 300 F higher than the experimental curve throughout the combustion zone. This may be due to heat loss from the sides of the experimental furnace, which, of course, could not be accounted for in the calculation considering only one dimension. It is difficult to account for this discrepancy by incorrect values of the coefficients, because the temperature in this region depends almost entirely on μ_1/G

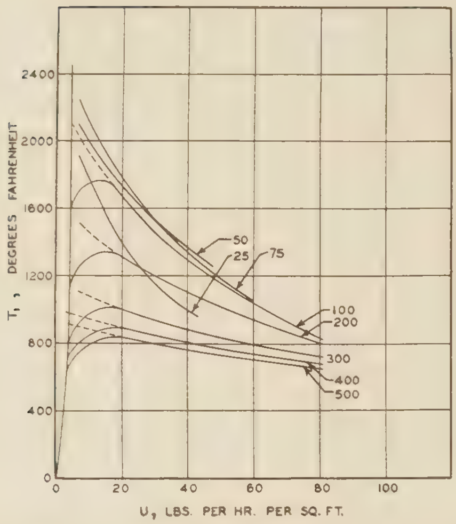

Fig. 4 Relation Between Temperature at the Plane of Ignition, and Rate of Ignition for Different Air-Flow Rates
(Numbers on curves represent air-flow rates in pounds per square foot per hour.)

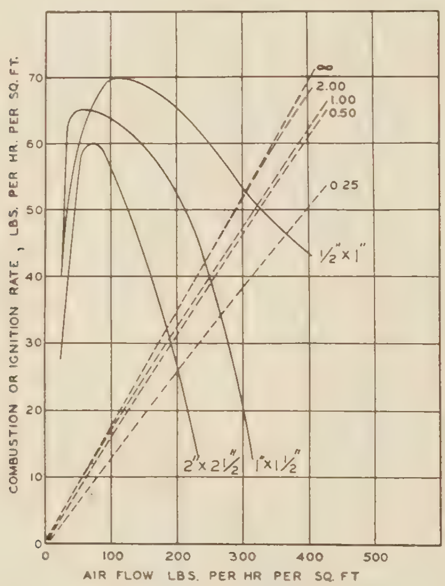

Fig. 5 Calculated Relation Between Combustion or Ignition Rates and Air-Flow Rates
(The solid curves give ignition rates, i.e., 1 in. × 1½ in. represents the rate of advance of the ignition zone for a fuel sized through 1½ in. and 1 in. screens. The dashed curves represent combustion rates; the numbers on each curve give depth of fuel bed in feet.)

and μ_2/G, and these are fixed quite exactly by the gas analysis given in Fig. 3.

(b) The slope of the calculated curve below the plane of ignition is steeper than that of the experimental curve. This is due to incorrect choice of the coefficients α and k. Evidently they should be still larger than those actually used, although those used are actually at the upper limits of what can be justified by existing measurements.

(c) The drop in temperature at the top of the bed ($x = 18$ in.) is much greater in the calculated than in the experimental curves. This is partially due to the same error as in (2), and also to the fact that insufficient allowance appears to have been made in the calculation for the decrease in heat loss by radiation from the top of the fuel bed due to the flame of combustible gases leaving the bed.

Comparison of the curves for unrestricted and restricted ignition shows that the temperature in the bed with restricted ignition is more than 300 F less than that with unrestricted ignition, even though the former bed is igniting fuel at only six tenths the rate at which the latter is. This difference represents the heat radiated downward to the grate by the bed with restricted ignition, and is the source of the destructive heating of the stoker parts so well known to stoker operators.

Fig. 3 shows the gas analysis at various points in the fuel bed. The analysis determined experimentally is given by the solid line, and that for both calculated cases is given by the dashed line.

It is to be noted that no correction has been made in the calculated analyses for the expansion of the gas due to the reaction forming carbon monoxide. This leads to an error, negligible at low CO concentrations, but appreciable at higher ones.

Fig. 4 shows the relation between T_i, U_i, and G determined by Equation [26]. By the use of a set of such curves as this, cal-

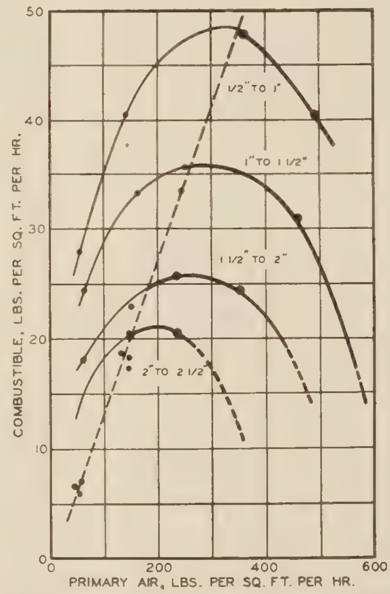

Fig. 6 Experimental Combustion and Ignition Rates in Relation to Air-Flow Rate as Given by Nicholls and Eilers (7)

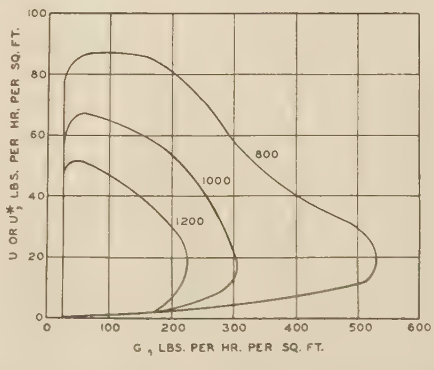

Fig. 7 Calculated Rates of Ignition in Relation to Air-Flow Rate for Various Ignition Temperatures
(Numbers on curves represent ignition temperatures, deg F.)

culated for various fuel sizes, the solid lines of Fig. 5 may be obtained by plotting U_i against G for any fixed value of T_i. Fig. 5 is to be compared with Fig. 6, the relation found experimentally between U_i and G (6, 7). The dashed lines of Fig. 5 represent the combustion rate, calculated from Equation [15] for various thicknesses of the combustion zone. They are to be compared with the sloping line of Fig. 6, in which, however, the combustion-zone thickness was not controlled, but was allowed to increase continuously. It will be observed that in the region covered by the curves of Figs. 5 and 6, there are no discrepancies that better knowledge of the coefficients may not be expected to remove.

Fig. 7 shows the relation between U_i and G for several different values of the ignition temperature, defining completely the area in which self-ignition by underfeed action is possible. This figure shows how important this characteristic is in determining the combustion properties of different fuels. Other significant properties of fuel beds that may be calculated by means of the expressions derived in this paper are discussed by the author in another paper (13).

Acknowledgments

The author wishes to acknowledge his indebtedness to Dr. H. H. Lowry, director of the Coal Research Laboratory, without whose encouragement this work would not have been completed; to Dr. Leo Kasehagen of this laboratory for his assistance in checking the mathematics; and to other engineers and scientists, including especially L. A. Shipman, of the Southern Coal and Coke Company, and P. Nicholls of the U. S. Bureau of Mines, whose discussions of this material have helped to clarify the significance of various factors.

Conclusions

The characteristics of pure underfeed combustion, calculated theoretically on the hypothesis that the fuel bed behaves like a heat-conducting solid in the interstices of which convection and combustion occur, have been shown to duplicate with considerable fidelity the experimental determinations of those characteristics.

The analysis is also immediately applicable to overfeed fuel beds by merely changing the sign of the combustion rate U, and making the necessary modifications of the coefficients occurring in the boundary conditions.

The results indicate the significance of various chemical and physical factors in determining the combustion characteristics of fuels, and show the need for research investigations of the heat-transfer coefficients in, and the thermal conductivity of, beds of broken solids.

The method of analysis may be applied only in a general way to real fuel beds, since these are not usually pure underfeed beds, but operate largely on a side-feed principle in which air and fuel move in directions roughly at right angles. The analytical investigation of this case is more complicated, but probably not beyond the possibility of solution.

Appendix

Unrestricted Ignition

The Constants of Equations [20a], [20b], and [20c]

The six constants A, B, C, D, E, and F are determined by the six equations obtained by substituting the expressions given in Equations [20a], [20b], and [20c] into the boundary conditions of Equations [8] and [19], and the continuity conditions given by Equation [21] and the paragraph preceding it.

These equations are

$$-\left(\frac{\beta+\rho U}{k}-b\right)A+cB-\frac{\beta+\rho U}{k}C=0 \ldots\ldots [1A]$$

$$e^{bl}\left[\left(b+\frac{\gamma}{k}\right)\cosh cl+c\sinh cl\right]A+e^{bl}\left[\left(b+\frac{\gamma}{k}\right)\sinh cl+c\cosh cl\right]B+e^{b(l-x_1)}\left[\left(b+\frac{\gamma}{k}\right)\cosh c(l-x_1)+c\sinh c(l-x_1)\right]D+e^{b(l-x_1)}\left[\left(b+\frac{\gamma}{k}\right)\sinh c(l-x_1)+c\cosh c(l-x_1)\right]E+\frac{\gamma}{k}F$$

$$=\frac{\left(\frac{\gamma}{k}-\frac{\mu_1}{G}\right)\left(\frac{\alpha}{Gc_p}-\frac{\mu_1}{G}\right)e^{-\frac{\mu_1}{G}(l-x_1)}}{\frac{u_1}{G}\left[c_2-\left(b+\frac{\mu_1}{G}\right)^2\right]}Q-\frac{\left(\frac{\gamma}{k}-\frac{\mu_2}{G}\right)\left(\frac{\alpha}{Gc_p}-\frac{\mu_2}{G}\right)e^{-\frac{\mu_2}{G}(l-x_1)}}{\frac{\mu_2}{G}\left[c^2-\left(b+\frac{\mu_2}{G}\right)^2\right]}R \ldots\ldots [2A]$$

$$\left(c^2+b^2-\frac{\rho U}{k}b-\frac{\alpha}{k}\right)A-c\left(\frac{\rho U}{k}-2b\right)B-\frac{\alpha}{k}C=0 \ldots\ldots [3A]$$

$$-C+D+F=\frac{\left(\frac{\alpha}{Gc_p}-\frac{\mu_1}{G}\right)Q}{\frac{\mu_1}{G}\left[c^2-\left(b+\frac{\mu_1}{G}\right)^2\right]}-\frac{\left(\frac{\alpha}{Gc_p}-\frac{\mu_2}{G}\right)R}{\frac{\mu_2}{G}\left[c^2-\left(b+\frac{\mu_2}{G}\right)^2\right]} \ldots\ldots [4A]$$

$$bD+cE=-\frac{\left(\frac{\alpha}{Gc_p}-\frac{\mu_1}{G}\right)Q}{c^2-\left(b+\frac{\mu_1}{G}\right)^2}+\frac{\left(\frac{\alpha}{Gc_p}-\frac{\mu_2}{G}\right)R}{c^2-\left(b+\frac{\mu_2}{G}\right)^2} \ldots [5A]$$

$$(c^2+b^2)D+2bcE=\left[\frac{\frac{\mu_1}{G}\left(\frac{\alpha}{Gc_p}-\frac{\mu_1}{G}\right)}{c^2-\left(b+\frac{\mu_1}{G}\right)^2}-1\right]Q-\left[\frac{\frac{\mu_2}{G}\left(\frac{\alpha}{Gc_p}-\frac{\mu_2}{G}\right)}{c^2-\left(b+\frac{\mu_2}{G}\right)^2}-1\right]R \ldots\ldots [6A]$$

where

$$Q=\frac{\mu_1 P_1}{k}\left(h_1+\frac{\mu_2 h_2}{(\mu_1-u_2)}\right)$$

and

$$R=\frac{\mu_1\mu_2 P_1 h_2}{(\mu_1-\mu_2)\,k}$$

The solution of this system gives the values of the constants in terms of the quantities b, c, μ_1/G, μ_2/G, β, and γ, but the result may be simplified by making use of the five following conventions

$$\tanh \sigma = \frac{\dfrac{\beta + \rho U}{k}\,\dfrac{\rho U + Gc_p}{\beta + \rho U + Gc_p} - b}{c} \qquad \text{[7A]}$$

$$\tanh s = \frac{b}{c} \qquad \text{[9A]}$$

$$\tanh \tau = \frac{\dfrac{\gamma}{k} + b}{c} \qquad \text{[8A]}$$

$$\tanh t_1 = \frac{b + \dfrac{\mu_1}{G}}{c} \qquad \text{[10A]}$$

$$\tanh t_2 = \frac{b + \dfrac{\mu_2}{G}}{c} \qquad \text{[11A]}$$

when the solution to Equation [16] may be written

(*a*) for the region $0 \leqslant x \leqslant x_1$

$$T = P_1 \frac{e^{bx}\cosh(cx+\sigma) - \dfrac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}}{e^{bl}\sinh(cl+\sigma+\tau) - \dfrac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}} \Bigg[h_1 \Bigg\{ \frac{1}{c_p + \dfrac{U}{G}\rho} \Bigg(\frac{e^{b(l-x_1)}\sinh[c(l-x_1)+\tau-s]}{\cosh s} - \frac{\dfrac{\gamma}{k}\sinh\tau}{b+\dfrac{\gamma}{k}} \Bigg)$$

$$- \frac{1}{\dfrac{c_p}{1-\mu_1/\dfrac{\alpha}{c_p}} + \dfrac{U}{G}\rho + \dfrac{\mu_1 k}{G^2}} \Bigg(\frac{e^{b(l-x_1)}\sinh[c(l-x_1)+\tau-t_1]}{\cosh t_1} - \frac{\left[\dfrac{\gamma}{k} - \dfrac{\mu_1}{G}\right]\sinh\tau}{b+\dfrac{\gamma}{k}} e^{-\frac{\mu_1}{G}(l-x_1)} \Bigg) \Bigg\}$$

$$- h_2 \Bigg\{ \frac{1}{c_p + \dfrac{U}{G}\rho} \Bigg(\frac{e^{b(l-x_1)}\sinh[c(l-x_1)+\tau-s]}{\cosh s} - \frac{\dfrac{\gamma}{k}\sinh\tau}{b+\dfrac{\gamma}{k}} \Bigg) - \frac{1}{1-\dfrac{\mu_2}{\mu_1}} \Bigg(\frac{1}{\dfrac{c_p}{1-\mu_2/\dfrac{\alpha}{c_p}} + \dfrac{U}{G}\rho + \dfrac{\mu_2 k}{G^2}}$$

$$\times \Bigg[\frac{e^{b(l-x_1)}\sinh[c(l-x_1)+\tau-t_2]}{\cosh t_2} - \frac{\left(\dfrac{\gamma}{k} - \dfrac{\mu_2}{G}\right)}{b+\dfrac{\gamma}{k}} e^{-\frac{\mu_2}{G}(l-x_1)} \sinh\tau \Bigg] - \frac{\dfrac{\mu_2}{\mu_1}}{\dfrac{c_p}{1-\mu_1/\dfrac{\alpha}{c_p}} + \dfrac{U}{G}\rho + \dfrac{\mu_1 k}{G^2}}$$

$$\times \Bigg[\frac{e^{b(l-x_1)}\sinh[c(l-x_1)+\tau-t_1]}{\cosh t_1} - \frac{\left(\dfrac{\gamma}{k} - \dfrac{\mu_1}{G}\right)}{b+\dfrac{\gamma}{k}} e^{-\frac{u_1}{G}(l-x_1)} \Bigg] \Bigg) \Bigg\} \Bigg] \qquad \text{[12A]}$$

(*b*) for the region $x_1 \leqslant x \leqslant l$

$$T = P_1 \Bigg\{ \frac{h_1 - h_2}{c_p + \dfrac{U}{G}\rho} \Bigg[1 - \frac{e^{b(l+x-x_1)}\sinh(cx_1+\sigma+s)\cosh[c(l-x)+\tau]}{\cosh s\left[e^{bl}\sinh(cl+\sigma+\tau) - \dfrac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}$$

$$- \frac{\dfrac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\left[e^{b(l-x_1)}\sinh\{c(l-x_1)+\tau-s\} - \dfrac{\gamma\sinh\tau}{\gamma+kb} e^{b(x-x_1)}\cosh\{c(x-x_1)-s\}\right]}{\cosh s\left[e^{bl}\sinh(cl+\sigma+\tau) - \dfrac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}$$

$$- \frac{\dfrac{\gamma\sinh\tau}{\gamma+kb}\left[e^{bx}\cosh(cx+\sigma) - \dfrac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\right]}{e^{bl}\sinh(cl+\sigma+\tau) - \dfrac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}} \Bigg] - \frac{h_1 + \dfrac{\mu_2 h_2}{(\mu_1-\mu_2)}}{\dfrac{c_p}{1-\mu_1/\dfrac{\alpha}{c_p}} + \dfrac{U}{G}\rho + \dfrac{\mu_1 k}{G^2}}$$

$$\left[e^{-\frac{u_1}{G}(l-x)} - \frac{e^{b(l+x-x_1)}\sinh(cx_1+\sigma+t_1)\cosh[c(l-x)+\tau]}{\cosh t_1\left[e^{bl}\sinh(cl+\sigma+\tau) - \frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}\right.$$

$$-\frac{\frac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\left[e^{b(l-x_1)}\sinh\{c(l-x_1)+\tau-t_1\} - \frac{\gamma\sin\tau}{\gamma+kb}e^{b(x-x_1)}\cosh\{c(x-x_1)-t_1\}\right]}{\cosh t_1\left[e^{bl}\sinh(cl+\sigma+\tau) - \frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}$$

$$\left.-\frac{\frac{\left(\frac{\gamma}{k}-\frac{\mu_1}{G}\right)\sinh\tau}{\frac{\gamma}{k}+b}\, e^{-\frac{u_1}{G}(l-x_1)}\left[e^{bx}\cosh(cx+\sigma)-\frac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\right]}{e^{bl}\sinh(cl+\sigma+\tau)-\frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}}\right]$$

$$+\frac{\frac{\mu_1 h_2}{\mu_1-\mu_2}}{\frac{c_p}{1-\mu_2/\frac{\alpha}{c_p}}+\frac{U}{G}\rho+\frac{\mu_2 k}{G^2}}\left[e^{-\frac{u_2}{G}(l-x)} - \frac{e^{b(l+x-x_1)}\sinh(cx_1+\sigma+t_2)\cosh[c(l-x)+\tau]}{\cosh t_2\left[e^{bl}\sinh(cl+\sigma+\tau) - \frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}\right.$$

$$-\frac{\frac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\left[e^{b(l-x_1)}\sinh\{c(l-x_1)+\tau-t_2\} - \frac{\gamma\sinh\tau}{\gamma+kb}e^{b(x-x_1)}\cosh\{c(x-x_1)-t_2\}\right]}{\cosh t_2\left[e^{bl}\sinh(cl+\sigma+\tau) - \frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}\right]}$$

$$\left.\left.-\frac{\frac{\left(\frac{\gamma}{k}-\frac{\mu_2}{G}\right)}{\frac{\gamma}{k}+b}\sinh\tau\, e^{-\frac{\mu_2}{G}(l-x_1)}\left[e^{bx}\cosh(cx+\sigma)-\frac{\beta\cosh\sigma}{\beta+\rho U+Gc_p}\right]}{e^{bl}\sinh(cl+\sigma+\tau)-\frac{\beta\gamma\cosh\sigma\sinh\tau}{(\beta+\rho U+Gc_p)(\gamma+kb)}}\right]\right\} \quad \ldots\ldots\ldots\ldots [13A]$$

In simplifying these expressions by the use of the device stated in the section "Solution of Differential Equations" of the paper, the second term in the denominator of each of the fractions within the brackets in Equation [13A] may be neglected by comparison with the first term.

RESTRICTED IGNITION

The Constants of Equation [27]

The three constants, A', B', and C' are determined by the three equations

$$-\left(\frac{\beta+\rho U}{k}-b\right)A' + cB' - \frac{\beta+\rho U}{k}C' = -\frac{\left(\frac{\mu_1}{G}+\frac{\beta+\rho U}{k}\right)Q'}{\frac{\mu_1}{G}\left[c^2-\left(b+\frac{\mu_1}{G}\right)^2\right]} + \frac{\left(\frac{\mu_2}{G}+\frac{\beta+\rho U}{k}\right)R'}{\frac{\mu_2}{G}\left[c^2-\left(b+\frac{\mu_2}{G}\right)^2\right]} \quad \ldots [14A]$$

$$e^{bl}\left[\left(b+\frac{\gamma}{k}\right)\cosh cl + c\sinh cl\right]A' + e^{bl}\left[\left(b+\frac{\gamma}{k}\right)\sinh cl + c\cosh cl\right]B' + \frac{\gamma}{k}C' = \frac{\left(\frac{\gamma}{k}-\frac{\mu_1}{G}\right)e^{-\frac{\mu_1}{G}l}}{\frac{\mu_1}{G}\left[c^2-\left(b+\frac{\mu_1}{G}\right)^2\right]}Q'$$

$$-\frac{\left(\frac{\gamma}{k}-\frac{\mu_2}{G}\right)e^{-\frac{\mu_2}{G}l}}{\frac{\mu_2}{G}\left[c^2-\left(b+\frac{\mu_2}{G}\right)^2\right]}R' \quad \ldots [15A]$$

$$\left(c^2+b^2-\frac{\rho U}{k}b-\frac{\alpha}{k}\right)A'-c\left(\frac{\rho U}{k}-2b\right)B'-\frac{\alpha}{k}C' = \frac{\left[\left(\frac{\mu_1}{G}\right)^2+\frac{\mu_1}{G}\frac{\rho U}{k}-\frac{\alpha}{k}\right]Q'}{\frac{\mu_1}{G}\left[c^2-\left(b+\frac{\mu_1}{G}\right)^2\right]}-\frac{\left[\left(\frac{\mu_2}{G}\right)^2+\frac{\mu_2}{G}\frac{\rho U}{k}-\frac{\alpha}{k}\right]R'}{\frac{\mu_2}{G}\left[c^2-\left(b+\frac{\mu_2}{G}\right)^2\right]} \quad [16A]$$

where $Q' = \frac{\mu_1 P_1}{k}\left(\frac{\alpha}{Gc_p}-\frac{\mu_1}{G}\right)\left(h_1+\frac{\mu_2 h_2}{\mu_1-\mu_2}\right)$ and $R' = \frac{\mu_1\mu_2 P_1}{(\mu_1-\mu_2)\,k}\left(\frac{\alpha}{Gc_p}-\frac{\mu_2}{G}\right)$

When this system is solved, it is found that the expression obtained for the temperature is identical with that given in Equation [13A], except that x_1 vanishes everywhere, and the coefficient of the first term, instead of being $(h_1 - h_2)/(c_p + U/G\rho)$ as it is in Equation [13A] is now

$$\frac{\left(1-\mu_1\Big/\frac{\alpha}{c_p}\right)h_1-h_2}{c_p+\frac{U}{G}\rho} \quad [17A]$$

The Separation and Emission of Cinders and Fly Ash

By ARTHUR C. STERN,[1] NEW YORK, N. Y.

The author discusses the size-frequency analysis of cinders and fly ash, and the variation of the efficiency of dust separation with varying dust-particle size. He shows how these two factors may be combined to determine the overall efficiency of separation. He outlines a rational method for the calculation of dust separation and emission in complex fuel-burning units, in which the dust originates in the furnace, and must pass, prior to its emission into the atmosphere, through numerous heat-absorbing units, including some in which a measure of dust removal may occur. He points out what experimental data must be made available to designers before they may fully utilize any method of predetermining the operating characteristics of equipment with respect to cinder and fly-ash emission. He attempts a theoretical analysis of the efficiency of dust separation in settling chambers, centrifugal concentrators, and cyclone separators.

THE emission of cinder and fly-ash particles from the stacks of fuel-burning plants, particularly steam-generating plants, presents a real problem both from the points of view of air pollution and power-plant operation. Therefore, it is desirable that engineers be able to predetermine the quantity and character of this emission as part of the regular procedure in designing any installation of fuel-burning equipment. A method for making the necessary calculation for this purpose is outlined in this paper. This method of analysis also allows calculation of the quantity and character of the dust separated out of the flue-gas stream at various points in its path from furnace to stack.

Nomenclature

- μ = diameter of dust particle, microns ($1\ \mu = 10^{-4}$ cm)
- A = dust loading at any instant of time, weight of dust per unit volume of flue gas
- k = definite size interval, for instance, from 50 μ to 100 μ, or from 100 μ to 200 μ
- A_k = dust loading within size interval, k
- α = dust in suspension in the flue gas entering the unit
- β = dust in suspension in the flue gas leaving the unit
- γ = dust separated out of the flue gas in the unit
- $A_\alpha = A_\beta + A_\gamma$
- $A_{k\alpha} = A_{k\beta} + A_{k\gamma}$
- ϕ = overall efficiency of separation at any instant of time $= \dfrac{100\ A_\gamma}{A_\alpha} = \dfrac{100\ A_\gamma}{A_\beta + A_\gamma} = \dfrac{100\ (A_\alpha - A_\beta)}{A_\alpha}$
- λ = size efficiency, the efficiency of separation of a definite size interval of the dust at any instant of time
- λ_k = efficiency of separation of size interval $k = \dfrac{100\ A_{k\gamma}}{A_{k\alpha}} = \dfrac{100\ A_{k\gamma}}{A_{k\beta} + A_{k\gamma}} = \dfrac{100\ (A_{k\alpha} - A_{k\beta})}{A_{k\alpha}}$
- d = per cent by weight of the dust within a size interval
- d_k = per cent by weight of the dust within the size interval $k = \dfrac{100\ A_k}{A}$
- D = cumulative per cent by weight less than stated size $= 100 - R$
- R = cumulative per cent by weight greater than stated size $= 100 - D$
- M_g' = geometric-mean particle size, microns
- b = experimental parameter
- n = experimental parameter
- v = flue-gas velocity, also dust-particle velocity, fps
- V, V_g, V_c = dust-particle velocity orthogonal to direction of flue-gas velocity, fps
- ρ = flue-gas density, lb per cu ft
- η = flue-gas viscosity, lb per ft sec
- δ = dust-particle density, lb per cu ft
- δ_g = geometric standard deviation
- g = acceleration due to gravity, ft per sec per sec
- h, h', h'', w, l, r = dimensions of settling chambers, centrifugal concentrators, and cyclone removers, ft
- P, F_g, F_c = forces acting on dust particle, lb
- p = per cent of flue gas from which dust is completely removed
- s = surface toward which dust separates
- U = number of revolutions of flue-gas stream in cyclone remover
- $1, 2, 3 \ldots w$ = subscripts designating a series of definite consecutive size intervals covering the entire range of sizes from $\mu = 0$ to $\mu = \infty$
- e = Napierian base

Equations for Combining Size Frequency and Size Efficiency

$$\phi = \lambda_1 d_{\alpha 1} + \lambda_2 d_{\alpha 2} + \lambda_3 d_{\alpha 3} + \ldots + \lambda_w d_{\alpha w} \ldots\ldots [1]$$

$$\phi = \frac{1}{\left[\dfrac{d_{\gamma 1}}{\lambda_1} + \dfrac{d_{\gamma 2}}{\lambda_2} + \dfrac{d_{\gamma 3}}{\lambda_3} + \ldots + \dfrac{d_{\gamma w}}{\lambda_w}\right]} \ldots\ldots [2]$$

$$\phi = (Y + 1)/Y \ldots\ldots [3]$$

---

[1] Engineer, Air Pollution Survey, New York City Health Department. Jun. A.S.M.E. Mr. Stern was graduated from Stevens Institute of Technology with an M.E. degree in 1930, and after graduation remained at Stevens Institute as research assistant to E. H. Whitlock in the division of smoke-abatement research of the mechanical-engineering department. He received his M.S. degree from Stevens Institute upon completion of the research program in 1933. After an interval of two years in engineering appraisal work for the J. G. White Engineering Corp., and independently for the New York Times Company, he resigned in 1935 to organize the present air-pollution survey program for the New York City Health Department.

Contributed by the Fuels Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

where $$Y = \left[\frac{\lambda_1 d_{\beta_1}}{1-\lambda_1} + \frac{\lambda_2 d_{\beta_2}}{1-\lambda_2} + \ldots + \frac{\lambda_w d_{\beta_w}}{1-\lambda_w}\right]$$

$$d_{k\alpha} = \frac{(1-\phi)}{(1-\lambda_k)}\, d_{k\beta} = \frac{\phi}{\lambda_k}\, d_{k\gamma} \ldots\ldots\ldots\ldots [4]$$

$$d_{k\beta} = \frac{(1-\lambda_k)}{(1-\phi)}\, d_{k\alpha} = \frac{\phi\,(1-\lambda_k)}{\lambda_k\,(1-\phi)}\, d_{k\gamma} \ldots\ldots\ldots [5]$$

$$d_{k\gamma} = \frac{\lambda_k}{\phi}\, d_{k\alpha} = \frac{\lambda_k\,(1-\phi)}{\phi\,(1-\lambda_k)}\, d_{k\beta} \ldots\ldots\ldots\ldots [6]$$

Calculation of Separation and Removal Efficiency

Equations [1], [2], and [3] allow the calculation of the overall efficiency of separation from size frequency and size efficiency, provided the latter is known for the entire range of sizes existing in the dust. Equations [4], [5], and [6], allow the calculation of unknown size frequency of dust at either the α, β, or γ location, (entering the unit in suspension, leaving the unit in suspension, or separated in the unit) from the size frequency of the known one of these three conditions and size efficiencies for the entire size range of the entering suspended dust. The value of ϕ for use in the latter three equations may be calculated from one of the first three equations.

Of the first three equations, Equation [1] is the simplest and the most useful for design purposes. It is possible to effect a further simplification by arbitrarily varying the limits of the consecutive size intervals, 1, 2, 3 . . . . w, so that all values of d_α are the same. That this can be done is evidenced by the fact that the sum of all values of d_α, from 1 to w, inclusive, must be 100 per cent. Therefore, dividing 100 per cent by the desired number of equal values of d_α will give the per cent of the total dust weight included in each interval. Thus, if it is desired to have ten equal intervals, each value of d_α will be 10 per cent. Under these circumstances w is 10 and Equation [1] will factor as

$$\phi = 0.10\,(\lambda_1 + \lambda_2 + \lambda_3 + \lambda_4 + \lambda_5 + \lambda_6 + \lambda_7 + \lambda_8 + \lambda_9 + \lambda_{10}) \ldots [7]$$

In Equation [7], λ_1 is the efficiency of separating dust of the size interval corresponding to the range of R between 0 per cent and 10 per cent, which may be considered equivalent to the efficiency of separating dust of the size corresponding to R = 5 per cent, etc. So that when values of λ for the particle sizes corresponding to each of the following values of R equal to 5, 15, 25, 35, 45, 55, 65, 75, 85, and 95 per cent are added, and the sum multiplied by 0.10, the value of ϕ is calculated. This method would be equally valid had the value of d_α been chosen so as to make w any number other than 10, as, for instance, 5 or 20. However, from a practical point of view, five values are too few for analytical accuracy, and twenty are too many for graphical accuracy.

The removal efficiency of a unit in the flue-gas path will equal the separation efficiency ϕ only if conditions in the unit are such that the dust separated is removed from the flue-gas path as rapidly as it separates out of the flue gas. If the unit has no provision whatsoever for the removal of the separated dust, its removal efficiency must be zero regardless of how high its separation efficiency may be, because with no provision for removing the separated dust, the only possible result is for the separated dust to pile unremoved and unremovable up to such a height that the flue gases must re-entrain the dust to keep the flue-gas path open. Instead of continuous removal of the dust as noted previously, the intermittent removal of separated dust by the use of hoppers, into which the dust separates and from which it is removed at intervals frequent enough to avoid piling up beyond the hopper top into the flue-gas path, may be provided and equivalent results obtained. In intermediate cases where the removal system is inadequate to handle the quantity of dust separated, it is possible to have a removal efficiency lower than the separation efficiency, but greater than zero. The preceding calculations have been based solely upon size frequency and size efficiency, both of which vary with the rate of combustion of fuel in the furnace, causing removal efficiency to vary with rating.

Experimental data on size efficiency and size frequency obtained at several ratings during the same series of tests is subject to an important source of error caused by the lapse of time after changing the rating before a steady state is reached. This lapse is generally greater than that necessary to bring combustion conditions to a steady state at the new rating, and is caused by the piling up of dust at such places as on the floor of horizontal ducts, on ledges, and in hoppers. In a straight rectangular horizontal duct, gas velocity is proportional to rating. However, any piling up of dust on the floor of the duct decreases the cross-sectional area available for gas flow and thus increases gas velocity for the same rating as compared with a dust-free duct. Thus, the piling up of dust on the duct floor has the same effect on velocity as increasing the rating, and contrariwise, any action of flue gases passing over a pile of dust in re-entraining some of the dust in the gas will tend to decrease the height of the pile, increase the cross-sectional area available for gas flow and decrease the gas velocity in the same manner as a decrease in rating. Since with other factors remaining the same, the lower the gas velocity, the greater will be the piling up—and the higher the velocity, the greater will be the re-entrainment—it is apparent that there will be in a given duct a critical velocity for each rating at which re-entrainment will balance piling up, and that this velocity will occur after the dust has piled up in the duct to a definite height for each rating. Beyond that height re-entrainment will balance deposition, but the decrease in cross-sectional area and the increased gas velocity will increase the draft necessary to move the flue gas through the duct over that of a dust-free duct. An increase of rating will re-entrain dust and a decrease of rating will pile up dust until the critical velocities are all established for their respective ratings. Thus, during the interim following a change of rating, until critical velocities are all established, the instantaneous dust loadings, sizings and efficiencies will be considerably different from those after the steady state has been reached. Therefore, it is important that the values which are used in these calculations be steady state values.

Starting with the knowledge of the quantity and size frequency of dust leaving the furnace, and the size-efficiency characteristics of each unit in the flue-gas path, it is possible by means of a step-by-step calculation to calculate, first the quantity and size frequency of the dust leaving the first unit in the flue-gas path and entering the second unit; then, that leaving the second unit and entering the third; and so on to that leaving the next to last unit and entering the last one, which in this case would be the stack. If it is then possible to perform similar calculations for the stack, the result will be the quantity and size frequency of dust emitted to the atmosphere.

It should be obvious from the preceding considerations, that dust-emission and separation problems in fuel-burning equipment are susceptible of rational analysis and simple calculation, provided there is available to the person making the calculations the following experimental data:

(a) The quantity and size frequency of dust leaving fuel-burning furnaces at various ratings.

(b) The size efficiencies of all units in the flue-gas path experimentally determined against dusts of similar particle density and particle shape to that for which the calculation is to be made.

Methods of Analyzing Size-Frequency Data

Size-frequency analyses of dust determine experimentally the relationship existing between d and μ by means of sieving, sedimentation, elutriation, microscopic sizing or any combination of these methods. These experimental data are best subject to analysis by the use of a tabular form such as Table 1, from which can be plotted a distribution curve, such as shown in Fig. 1, which for a normal dust, is skewed as shown. Experience has proved that plotting these data on semilogarithimic paper serves to remove the skewness to a marked degree, so that plotting the cumulative percentage by weight, R, against μ on a logarithmic scale yields a curve, as shown in Fig. 2, from which may be obtained the ten values of μ corresponding to the specified values of R needed for the determination of ϕ using Equation [7].

Loveland and Trivelli (1)[2] have analyzed many different

methods whereby mathematical expression may be given to curves of the type shown in Figs. 1 and 2, with particular emphasis on expressions of sufficient simplicity that the parameters governing the expression would be useful as explicit constants for comparison and study. They discuss particularly the application of formulas developed by analysis of the relationship of the empirical distribution to that of "the normal" La Place-Gaussian law. Hatch (2, 3) and Choate (2) showed the usefulness of one of this type of expression that had been previously used by Hazen (4) and others. It is the logarithmic normal probability relationship

$$R_1 = \int_{\mu=\infty}^{\mu_1} \left[\frac{100}{\log \delta_g \sqrt{(2\pi)}} e^{-(\log \mu - \log M_g')^2/2\log^2 \delta_g} \right] d\mu. . [8]$$

Their method involves the plotting of R-μ data on logarithmic-probability paper, shown in Fig. 3; the drawing of a straight line through the plotted points, and calculating two parameters of the straight line; M_g', the geometric mean, which is the value of μ when $R = 50$ per cent, and δ_g the geometric standard deviation, which is the ratio of the value of μ for $R = 15.87$ per cent to the value of μ for $R = 50$ per cent. Since probability coordinates are symmetrical about the line for $R = 50$ per cent, δ_g also is the ratio of the value of μ for $R = 50$ per cent to the value of μ for $R = 84.13$ per cent. This method has been previously applied to cinders and fly ash by the author (5).

It is obvious that if the data plotted on logarithmic-proba-

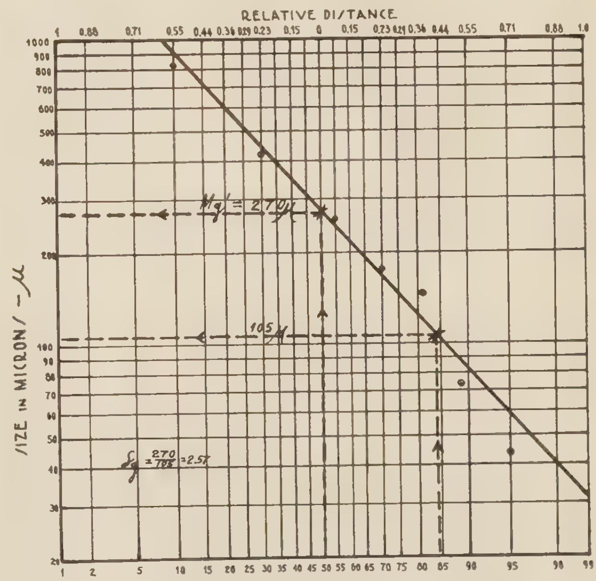

Fig. 3 Cumulative Size-Frequency Distribution on Logarithmic-Probability Coordinates of Dust Described in Table 1 and Plotted in Figs. 1 and 2

(The dotted lines are those necessary for the calculation of M_g' and δ_g.)

bility paper do not plot as a substantially straight line, they do not obey Equation [8], in which event M_g' and δ_g are meaningless and should not be calculated. The simplest method of using the parameters M_g' and δ_g to reconstruct the R-μ curve is to utilize a sheet of logarithmic-probability paper. First locate the point $\mu = M_g'$, $R = 50$ per cent; then the point $\mu = M_g'/\delta_g$, $R = 84.13$ per cent; then draw a straight line through these points. From this straight line, values of μ corresponding

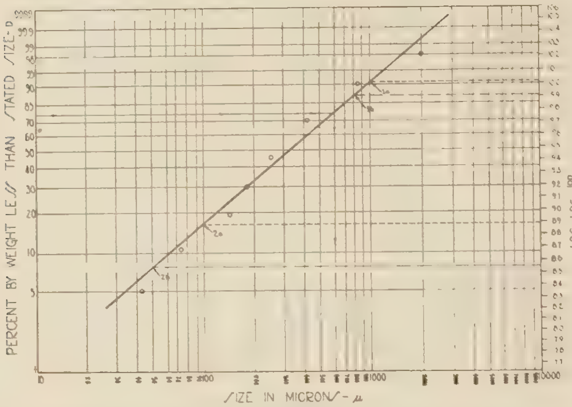

Fig. 4 Cumulative Size-Frequency Distribution on Log μ — (Log Log 100/R) Coordinates of Dust Described in Table 1 and Plotted, in Figs. 1, 2, and 3

(The dotted and dashed lines are used in the calculation of Table 3 by the simple and general methods, respectively. The solid line with arrows shows that the corresponding value of μ for D = 75 is 600 microns. This is to be compared with the similar result obtained by the use of Fig. 5.)

to R = 5, 15, 25 .... 95 per cent may be read directly for use in Equation [7].

Rosin and Rammler (6) have recommended an empirical expression for use instead of Equation [8]. It is

$$R = 100e^{-b\mu^n} \qquad \text{[9]}$$

They state: "It proved to be applicable without exception to cement, gypsum, magnesite, clay, dye stuffs, pulverized coal, in short, to all powdered materials of practical importance, down to the region of the very finest particles which could only be classified by sedimentation, as well as to the numerous methods of grinding employed such as sieveless tube mills with wet and dry grinding; both continuous and batch grinding, air-swept tube mills, centrifugal mills (Fuller and Raymond mills), with sieve and air separation, ring-roll mills (Rema and Mexican mills), impact mills of varied construction, and finally air-jet mills. In nearly every case the discrepancies between calculated and measured values are not more than 1 to 2 per cent of the total weight, seldom 3 per cent or more, and therefore, lie within the limits of accuracy of the methods of analysis employed (sieving, air elutriation, water elutriation and sedimentation).

"It is thus possible to state the law: The exponential $R = 100\, e^{-b\mu^n}$ is a universal law of size distribution valid for all powders, irrespective of the nature of the material and the method of grinding. The exponent n lies for the most part between 1 and 1.35. The parameter b varies over a much larger range."

In order to visualize the physical significance of the experimental parameters, n and b, it is necessary to note that the distribution curve in Fig. 1 shows a maximum, and the cumulative size-frequency curve in Fig. 2 shows a corresponding point of inflection. Rosin and Rammler (6) have shown that the maximum on the distribution curve and the point of inflection on the cumulative curve are possible only with $n > 1$. When $n = 1$, the maximum occurs at a particle size of zero microns, and as n increases the maximum occurs at increasingly larger particle sizes, obeying the equation

$$\mu_{\max} = \sqrt[n]{\left(\frac{n-1}{bn}\right)} \qquad \text{[10]}$$

Values of n less than 1 have no real maxima, therefore define impossible distributions.

By twice taking logarithms of Equation [9], Equation [11] is obtained

$$\log\log 100/R = n\log\mu + (\log b + \log\log e) \qquad \text{[11]}$$

from which it may be seen that a linear relation exists between [log log (100/R)] and log μ, with the parameter n as the slope, and the expression (log b + log log e) as the intercept. Therefore on coordinates such as shown in Fig. 4, having uniform increments of [log log (100/R)] as shown in Table 2 as ordinates, Equation [9], expressing the relationship between R and μ will plot as a straight line, and n and b will completely describe the size frequency of a dust which fits these coordinates, just as M_g' and δ_g describe a dust fitting logarithmic-probability coordinates, since only one straight line can be drawn having a particular set of parameters. Values may be determined beyond the range of the experimental data on either of these coordinates by extrapolation, using a projection of the straight line.

It is preferable to first plot experimental data on the [log log(100/R): log μ] coordinates, then fit the best straight line to these points, and last, to pick two points from that straight line for use in calculation. The reason for this preferential procedure is that the choice of any two experimental points not falling exactly on the line implies that the straight line goes through these two points, which, for the typical analysis plotted as Fig. 4, is obviously not the case. When these two points, whether experimental or from the straight line, are substituted in the two following equations, using Table 3, n and b may be readily calculated. These equations are

$$n = \frac{\log\log(100/R_1) - \log\log(100/R_2)}{\log\mu_1 - \log\mu_2} \qquad \text{[12]}$$

$$b = \text{antilog}\,[\log\log(100/R_1) - n\log\mu_1 - \log\log e] \qquad \text{[13]}$$

Use of these equations is simplified if points are picked from the straight line only at values of μ which are whole powers of 10 so that the resulting logarithms of μ become integers. If the

TABLE 3 CALCULATIONS OF THE CONSTANTS n AND b

		Simple method	General method
μ_1		1000	800
μ_2		100	50
$\log\log\left(\frac{100}{R_1}\right)$	A	10.020	9.910
$\log\log\left(\frac{100}{R_2}\right)$	B	8.890	8.550
A-B	C	1.130	1.360
$\log\mu_1$	D	3.000	2.903
$\log\mu_2$	E	2.000	1.699
D-E	F	1.000	1.204
n	C/F	1.130	1.130
$n\log\mu_2$	G	2.260	1.920
$\log\log e$	H	9.638	9.638
$G + H$	I	11.898	11.558
$B + 10$	J	18.890	18.550
J-I	K	6.992	6.992
b	antilog (K)	0.000982	0.000982
n		1.130	1.130
b		0.000982	0.000982

Note: Two sets of values of R and μ were used in the calculations, as shown in Fig. 4. Points with subscripts a were used in the simple-method calculations, and points with the subscript b were used in the general-method calculation.

experimental points are scattered so that no representative straight line can be drawn through them, no attempt should be made to calculate parameters, because under these conditions the chosen exponential function evidently cannot be made to express the R-μ relationship implicit in the data.

A graphical means for the solution of Equation [9] can also be shown. Fig. 5 yields a series of simultaneous values of R and μ corresponding to any set of values of n and b. With the exception of the lines marked $R = 2$ and 98 per cent, the remaining ten lines allow the determination graphically of ten values of μ corresponding to $R = 5, 15, 25 \ldots\ldots 95$ per cent which were previously noted as necessary for the simplified calculation of ϕ using Equation [7].

It should be noted that where the 50 per cent size of any cinder or fly-ash sample is less than 74μ in the case of a screen analysis with 200 mesh as the finest screen (43μ with 325 mesh as the finest screen) no data can be available from the screen analysis for the other 50 per cent or more by weight of the dust. Practically all fly-ash and suspended-cinder samples are in this category. Cinders that separate out of flue gas are coarser, however, and generally have more than 50 per cent by weight

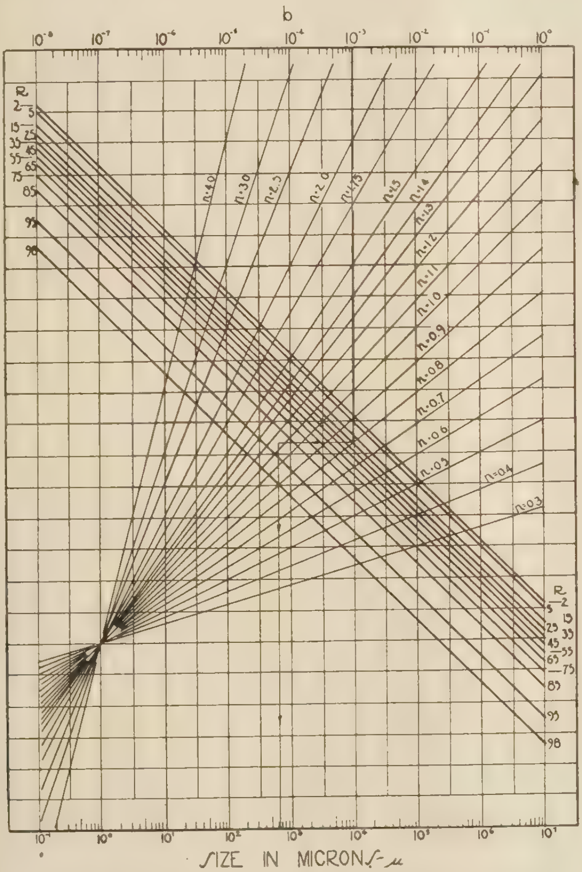

Fig. 5 Chart for Graphical Solution of $R = 100e^{-b\mu n}$

(From the value of b on the top axis drop a vertical line to the value of R on the parallel diagonal lines, then project a horizontal line to the value of n on the diagonal fan of the lines, then drop a vertical line to the unknown value of μ on the bottom axis. The values of b and n illustrated are $b = 0.000982$ and $n = 1.130$ from Table 3. The value of R is 25 ($D = 75$) and the corresponding value of μ is 600 microns, the same as obtained in Fig. 4.)

of particles with diameters $> 43\mu$, therefore, screen analyses of them generally yield sufficient points for accurate plotting. A study of 46 such sieve analyses of cinders from hoppers of stoker-fired boilers showed the following variability of n: 92 per cent of the samples between 0.88 and 2.23; 70 per cent between 1.07 and 1.99; and 45 per cent from 1.50 to 1.99. The variability of b was: 91 per cent between 0.0073 and 0.0000001; 82 per cent between 0.0073 and 0.0000012; and 45 per cent from 10^{-4} to 10^{-5}. Even the 18 per cent of these 46 dusts having values of n less than 1, the extrapolations of which are evidently not correct, nevertheless yield parameters which do describe the known portion of the distribution and do allow reasonably exact interpolation.

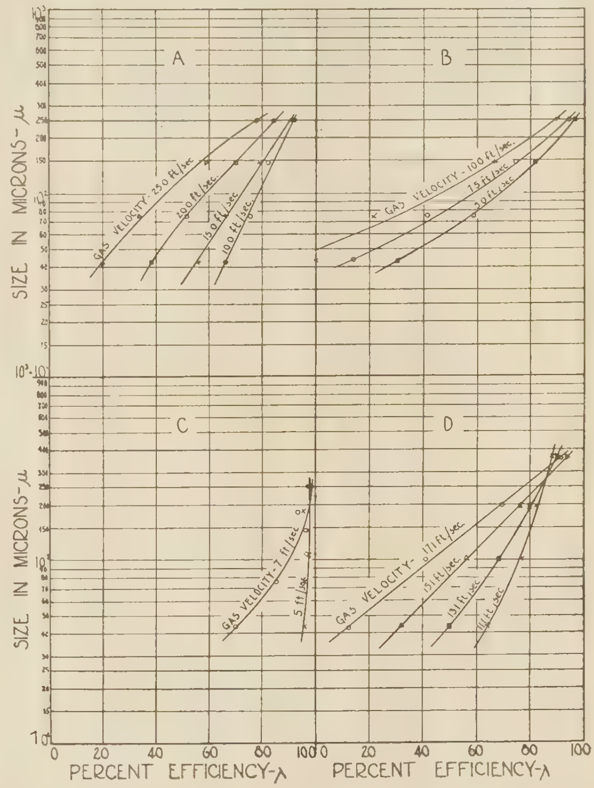

Fig. 6 Experimental Size-Frequency Characteristics for Actual Installations of Cinder and Fly-Ash Removers

Experimental Determination of Size Efficiency

The variation of λ_k with temperature, pressure, density, and viscosity within the small range possible in the case of flue gas is negligible compared with the variation with respect to particle size and flue-gas velocity. Size-efficiency characteristics of four typical dust removers A, B, C, and D are shown in Fig. 6. Removers B and C are of the dry mechanical type, whereas removers A and D are of the water-level impingement type without sprays or wetted surfaces. In all of these units, efficiency falls off with decreased particle size. Also in all of them, removal is centrifugal, and should theoretically have an increased removal efficiency with increased gas velocity. However, in each, the efficiency falls off with increasing flue-gas velocity for particles smaller than 200μ. In the case of remover C, efficiency increases with velocity over 200μ; in remover D, efficiency increases with velocity for particle sizes over 350μ; in remover A, the particle size beyond which efficiency increases with velocity is 450μ; while in remover B there is no evidence of this occurring at any particle size.

Thus, the velocity-efficiency characteristic is according to theory for the larger-sized particles, but not for the finer ones.

From considerations such as these, it should be obvious that only experimentally determined values of size efficiency should be used for design purposes.

Graphical Methods for Determination of Removal Efficiency

Figs. 2, 3, 4, or 5, may each be combined with an experimentally determined size-efficiency curve such as Fig. 6 so that a complete graphical solution of ten values of λ needed for the solution of Equation [7] may be effected on but one chart. The combination of charts of the type of either Figs. 2, 3, or 4 with one of the type of Fig. 6 allows the graphical solution of ϕ for one particular unit and one particular dust. However, to allow the graphical solution of the efficiency of one particular unit against any possible dust, it is necessary to combine a chart of the type of Fig. 6

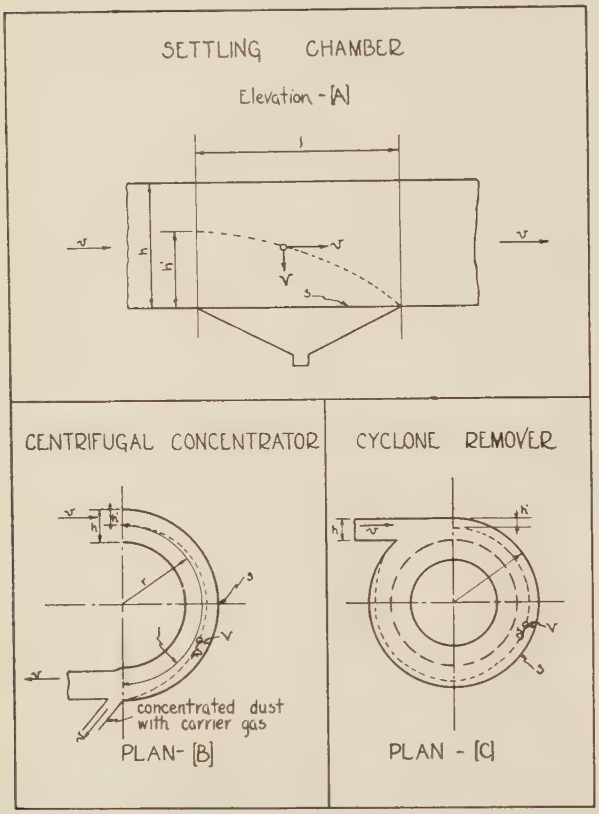

Fig. 7 Theoretical Motion of Dust Particle in (A) Settling Chamber, (B) Centrifugal Separator, and (C) Cyclone Remover

(A is an elevation view; B and C are plan views; V is orthogonal particle velocity. v is both particle and flue-gas velocity. h, h', l, and r, are the physical dimensions of the unit.)

with Fig. 5. Charts of wholly experimental origin combining Fig. 2 with Fig. 6 have already been put to use to solve design problems. In the author's opinion charts combining with Fig. 6 either Fig. 4 or Fig. 5, or the graphical representation of some other equation that may be later shown to more accurately fit experimental data, deserve a trial to determine whether or not they are as useful as they appear at present.

Theoretical Derivation of Size Efficiency

Theoretical derivations are based upon many simplifying assumptions, such as the absence of eddy currents; the absence of turbulent re-entrainment of separated dust; and the presence of a uniform distribution of dust and gas velocity. A theoretical approach such as the following one, however, does provide a rational basis for the interpretation of experimental data.

If flue gas passes through a unit at velocity v, so that the dust within the size interval k suspended in p per cent of the gas is completely separated in the unit, and the dust within the same size interval, suspended in the remaining $(100—p)$ per cent remains in suspension, the size efficiency of the unit for size interval k must equal p per cent. Under the assumed conditions of uniform gas flow, p per cent of the gas will flow through a cross-sectional area of phw, while the remainder of the gas flows through an area of $(100—p)\,hw$. If it be assumed that the gas flows in two nonmixing strata, both of width w, one will have a height $h' = ph = \lambda_k h$, and the other $h'' = (100—p)\,h = (100—\lambda_k)h$. Thus, it is obvious that

$$\lambda_k = h'/h \qquad [14]$$

Every particle of size interval k, in gas strata h' must thus reach removal surface s, as shown in Fig. 7, within length l, because under the assumed conditions, a particle not reaching s, cannot be considered as removed from the gas stream. Similarly, none of the particles in stratum h'' may reach s within the distance l, although they may reach it at any point beyond l. Therefore, a particle on the boundary between stratum h' and stratum h'' must just reach the removal surface at distance l. The time taken by one of the latter particles to travel distance l will be l/v seconds, assuming that the particle travels at the same velocity as the flue gas. The time taken for the same particle to travel distance h', orthogonal to the direction of v, will be h'/V seconds where V is the orthogonal particle velocity. These two times must be equal, so that

$$h' = \frac{Vl}{v} \qquad [15]$$

and, substituting in Equation [14]

$$\lambda_k = V\left(\frac{l}{vh}\right) = f(\mu)\left[\frac{l}{vh}\right] \qquad [16]$$

since, as will be later demonstrated, all other conditions remaining constant, V is a function of μ.

Graphical Determination of Theoretical Size Efficiency

Equation [16] may be solved graphically by the use of Fig. 8 which consists of a series of V-λ characteristics for various values of the ratio (l/vh), and a series of V-μ characteristics for various combinations of forces causing separation both plotted on the same coordinates, so that a value of λ_k may be obtained directly from a corresponding value of μ on but one chart. Fig. 8 thus represents the theoretical λ_k-μ relationship just as Fig. 6 represents the experimental one.

The ratio (l/h) will, in general, vary between 1 and 25, depending upon design conditions. The usual range for v is from 1 to 100 fps, so that the normal range of the ratio (l/vh) will be from 0.01 to 25. When $\lambda_k = 1$ and $(l/vh) = 0.01$, $V = 100$ fps; whereas when $\lambda_k = 1$ and $(l/vh) = 25$, $V = 0.04$ fps. The effect of a higher value of V in both these cases would be to make $\lambda > 1$ which is an impossibility meaning that 100 per cent separation is effected in a distance less than l. In the case of gravity settlement, $V = 0.04$ for a particle of about 15μ and $V = 50$ for a particle of about 2000μ. Although beyond 2000μ, particulate matter can scarcely be called dust, $V = 100$ for a hypothetical particle of $10{,}000\mu$.

Settling Chambers

Any horizontal run of duct or breeching such as that shown

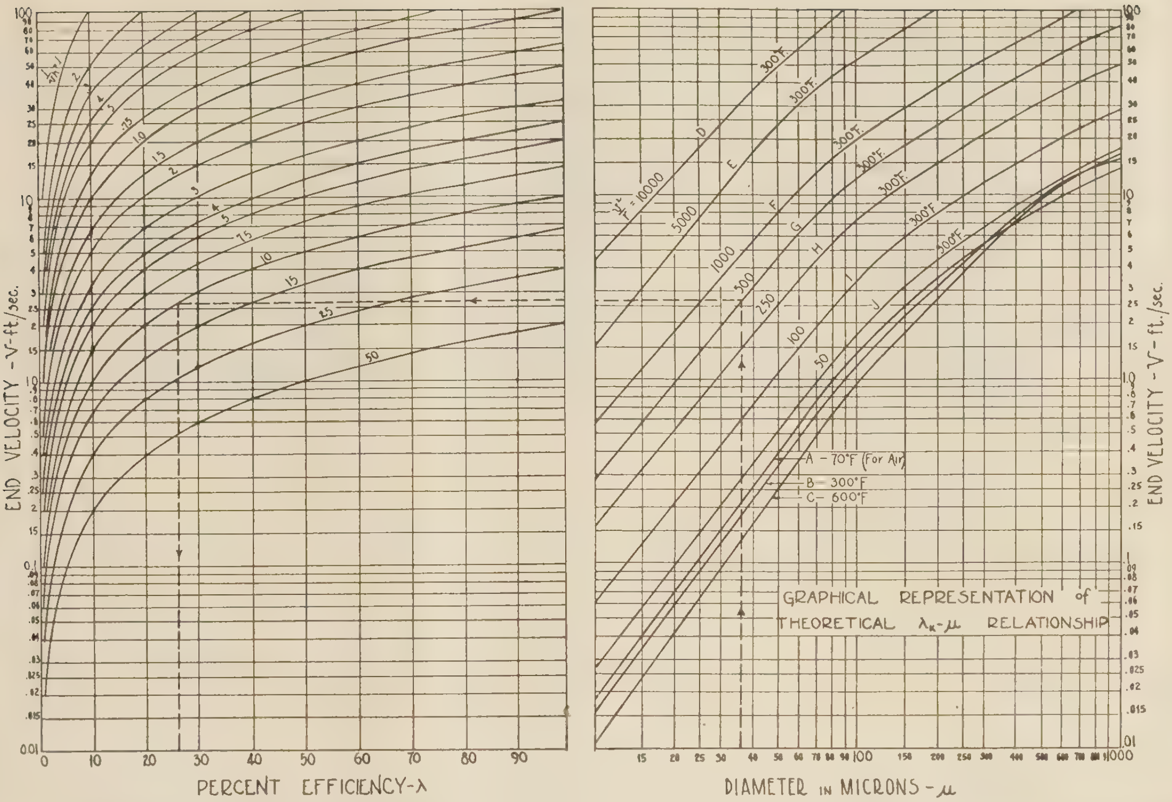

Fig. 8 Theoretical Size-Frequency Characteristics of Settling Chambers, Centrifugal Concentrators and Cyclone Removers
(The dashed line shows a typical calculation.)

in Fig. 7*A* will act as a dust remover if it is provided with hoppers for the continuous or intermittent removal of the separated dust. The ratio (l/vh) will be made up of v the average velocity; h the height of the duct; and l the distance from the beginning to the end of that portion of the duct provided with hoppers. The gravity-settling velocity V_g is obtained by solving for V after equating the force of the gas resisting particle motion

$$P = 9.84 \times 10^{-6} \frac{\pi\mu\eta V}{g}\left[1 + 0.14\left(\frac{\mu\rho V}{\eta}\right)^{0.7}\right] \ldots\ldots [17]$$

to the weight of the particle which is the force on the particle causing motion toward surface s. This force is

$$F_g = 5.88 \times 10^{-18}\,\pi\,\mu^3\,(\delta - \rho) \ldots\ldots\ldots\ldots [18]$$

Croft (7) has effected this solution of V for the range $\mu = 10^{-1}$ to $\mu = 10^4$ for air at 70 F and flue gas at 300 F and 600 F. These V_g-μ curves are reproduced for the range $\mu = 10$ to $\mu = 10^3$ as curves A, B, and C of Fig. 8.

In Equations [14] to [19], inclusive, particle density δ, gas density ρ, gas viscosity η, acceleration due to gravity g, velocities v and V, lengths l and h, and forces P and F are all in foot-pound-second units, but μ is in microns.

Centrifugal Concentrator

Any bend in a duct or breeching such as Fig. 7*B* will tend to concentrate dust toward its outer wall due to centrifugal force. If this outer stratum of flue gas containing the bulk of the dust is removed from the main stream of flue gas and its entrained dust completely separated in an auxiliary unit of equipment, the effect will be the same as if there had been a hopper built into the duct to remove the dust as soon as it reached removal surface s. In this case v and h have the same significance as in gravity settlement and l is the mean length of flue-gas path from the point where the bend starts to the point where the bend stops.

The force of gravity F_g on the particle shown in Fig. 7*B*, which is a plan view, is orthogonal to both v and V, and therefore must be neglected in calculating V. However, had Fig. 7*B* been an elevation view, the force of gravity would still have been neglected even though it is no longer orthogonal to V, both because its value is small compared to the centrifugal force, and because it acts in different directions with respect to surface s above and below the center line. The centrifugal settling velocity V_c is thus obtained by solving for V after equating Equation [17] to the centrifugal force on the particle causing motion toward surface s. The centrifugal force is

$$F_c = 35.5 \times 10^{-18} \frac{\pi\mu^3\,\delta v^2}{6\,gr} \ldots\ldots\ldots\ldots [19]$$

Assuming flue gas at 300 F, the V_c-μ relationship has been calculated for a number of different values of the ratio (v^2/r), and has been plotted as D, E, F, G, H, I, and J, in Fig. 8.

Cyclone Remover

The cyclone remover shown in Fig. 7*C*, is similar to the centrifugal concentrator except that the dust, after having concentrated on removal surface s falls by gravity into a hopper bottom integral with the cyclone, and secondly, that the gas makes several complete revolutions before entering the axial exhaust, so that distance l is indeterminate. Rosin, Rammler, and Intelmann (8) have attempted a theoretical solution of the cyclone

using an approach slightly different from that of Equation [16]. Their assumptions, however, are of use in this type of solution. These are that the stream of flue gas, which enters through a rectangular entrance duct of dimensions h and w, retains these two dimensions as it spirals unconstrained down the wall of the cyclone; that succeeding revolutions of this spiral are adjacent but do not mix; that the radius of the cyclone may be used as radius of curvature of this spiral; that the length of flue-gas path for one revolution of the spiral be the circumference of the cyclone; that there are a whole number of these revolutions U; and that the inlet gas velocity be considered to continue throughout the spiral.

Thus to obtain the ratio (l/vh), h is the width of the inlet duct, v is the velocity through the inlet duct, and $l = 2\pi rU$ where r is the radius of the cyclone and U is the number of revolutions of the gas in the cyclone. There is no rational method for estimating U, so that until experimental data can be correlated with theory a value of U from 2 to 4 seems reasonable. The value of V_c is obtained, as in the previous case of the centrifugal concentrator, from curves D, E, F, G, H, I, and J of Fig. 8.

It should be noted that the method for calculating cyclone efficiency as given by the author is at variance, in its assumptions with the vortex theory of cyclone collection. Vortex theory (the inverse relationship between gas velocity and radius, known to exist in cyclones) is neglected by assumptions of constant v and V. However, all attempts to incorporate this concept into these simplified methods of calculation have resulted in solutions too complicated to use.

Architect's Perspective Drawing of Springwells Station, Showing Major Plant Structures

The Springwells Station of the Detroit Department of Water Supply

By WILLIAM C. RUDD,[1] and BERNARD J. MULLEN,[2] DETROIT, MICH.

The Board of Water Commissioners of the City of Detroit anticipated the need of increasing the water-supply facilities for the city nearly 20 years ago and in the year 1919 ordered that engineering studies be made. As a result of these studies an additional water-supply system was authorized in 1924 at an estimated cost of $30,000,000. The project included a new river intake of 940 million gallons daily capacity, tunnels in sizes of 12 ft to 15½ ft diameter, about 12 miles long, a new pumping plant for 400 million gallons daily, filtration plant, and 16,500-kw steam-operated power plant. The new works were substantially completed in 1931 and placed in partial operation, but due to the depression, the plant was not placed in continuous service until 1935.

This paper discusses the various problems and engineering studies made in connection with the design and construction of a large modern water-works plant, with especial reference to the hydraulic and mechanical features of the pumping plant and the mechanical and electrical characteristics of the steam-operated power plant.

The pumping plant consists of raw-water pumps for delivering river water from the intake and tunnel system to the filter plant and also the filtered-water pumps to force water supply to the city distribution system. All pumps are housed in one building about 400 ft long by 100 ft wide. There are 26 centrifugal pumps varying in size from 7 to 60 million gallons daily each. The pumps are driven by synchronous and induction motors.

Power for the pump motors is produced in a steam turbogenerator plant, exclusive of a small portion that is secured from a central-station source. The power plant is adjacent to the pumping plant and consists of two 5000-kw and three 500-kw steam turbogenerators, two 90,000-lb per hr steam boilers and related equipment, together with a 5000-kw transformer for central-station power.

This paper deals with purchase of pumping and power-plant equipment secured in competitive bidding, with some of the major equipment secured on evaluated bids and with bonuses and penalties applied to contractor's guarantees. The paper also outlines the results of field acceptance tests for pumps, turbines, and boilers and gives the resulting bonuses and penalties applied to the various contracts. The paper also discusses the general plant-operating economies for a one-year period.

The Springwells Station of the Detroit Department of Water Supply was considered in the early 1920's as a means of augmenting the water supply of a rapidly increasing population in Detroit and vicinity. The phenomenal growth of the automobile industry together with new manufacturing plants attracted by the unique industrial conditions of this area, all served to focus attention upon the need for enlarged water-supply facilities.

He was formerly engaged as assistant engineer of water supply for the Louisville & Nashville Railroad Co., Louisville, Ky. He has been associated with the Detroit Department of Water Supply for the past 12 years.

[2] Chief Plant Engineer, Springwells Station of the Detroit Department of Water Supply. Mem. A.S.M.E. Mr. Mullen is a graduate of the University of Michigan in civil engineering. He was formerly employed for five years with the Detroit Edison Company. He has been associated with the Detroit Department of Water Supply for 16 years, the last two years in his present capacity.

Contributed by the Hydraulics and Steam Power Divisions for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Until 1931, when the Springwells Station located in the western section of Detroit was placed in partial operation, the Detroit area was supplied only from the Water Works Park Station situated on the east side of the city close to the Detroit River. Proposals considered for future needs also include the possibility of locating a third pumping and filtration station in the northeast section of the city.

Three sources of raw-water supply were considered, namely, Lake Huron, Lake St. Clair, and the Detroit River. The last-named source is already serving the existing Water Works Park Station. Because of the extremely high cost of constructing

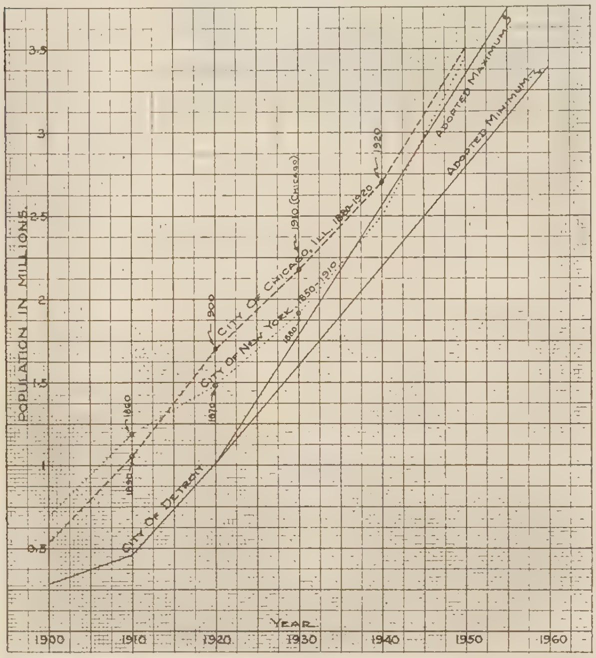

Fig. 1 Shows Estimated Population Curves for Detroit for 1900–1960, and Comparison With Chicago 1880–1920, and New York City 1850–1910

long connecting tunnels to the lakes and the increased pumping plants costs the head of Belle Isle in the Detroit River was chosen as the source of supply. This location was deemed adequate to supply the contemplated water requirements up to 1960, by which time shifting population and industrial changes might necessitate substantial revision in policy on plant extension. Studies of population growth in Chicago and other large cities indicated that the number of people in greater Detroit and the 300 square miles embraced by the water service might reach 3.4 millions by 1960, as shown in Fig. 1. The annual increase in water consumption corresponding to this growth and based upon a pumpage of 152 gal per capita daily, amounts to 10 or 12 million gallons per day (mgd) for each succeeding year.

The average annual consumption of water in the objective year, 1960, was estimated from these data at 520 mgd. Studies of the existing plant, modernized to increase its capacity, and of the sites chosen for the two new plants considered in conjunction with several other factors, showed that this average daily capacity of 520 mgd could be divided economically as follows: Water Works Park Station, 220 mgd; Springwells Station, 180 mgd; the future Northeast Station, 120 mgd. Estimates based on recorded daily-load curves and the full use of the Springwells site indicated that the raw-water pumping plant and filter plant should be designed for 135 per cent and the filtered-water pumping plant and distribution system should be designed for 180 to 190 per cent of the average daily water requirements.

The Springwells Station includes raw- and filtered-water pumping plant, filtration and electric-power-generating plants. Raw water flows by gravity from the Belle Isle intake through a tunnel extending under the City of Detroit to the inlet well of the station. A low-lift pumping plant takes water from this well and discharges it into two conduits leading under the power plant to the mixing chamber, coagulation basin, and the filter plant. Filtered water passes either to storage or to the suction of the high-lift pumps discharging into the distribution system. Fig. 2 is a diagrammatic layout indicating the flow pattern described later at greater length.

Several technical papers and articles describing some of the hydraulic- and civil-engineering features of the Springwells Station have already been published. The bibliography[3] included in this paper for convenience of those who wish to study design and operation further, lists these publications and others to which reference is made.

While the present paper gives a brief account of the hydraulic and civil-engineering features of the project, the primary purpose is: (*a*) To review the reasons for choosing motor-driven centrifugal pumps for both the high- and low-lift sections of the pumping station, giving an account of this equipment and its characteristic performance; (*b*) to describe the electrical generating plant built on the site, with provision for limited emergency service from a central-station supply; (*c*) to compare the expected performance of the station and its equipment with test results and with operating results obtained to the present time.

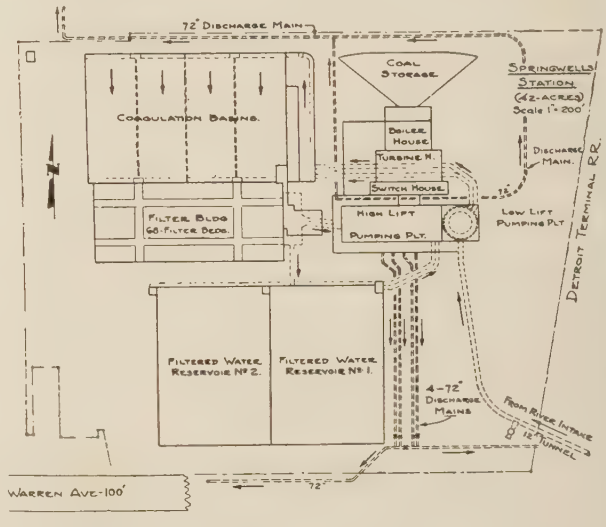

Fig. 2 Shows Flow of Water From River Intake to Springwells Station and Route of Raw and Filtered Water Through Various Plant Structures and Thence to Water-Distribution System

1 HYDRAULIC AND CIVIL-ENGINEERING FEATURES

The principal hydraulic and civil-engineering features of the plant are: (*a*) the river-water intake and tunnel to the screen chamber, (*b*) the land tunnels to the pumping station, (*c*) the low-lift plant, (*d*) the filtration plant, and (*e*) the high-lift plant feeding the city mains. Each of these features is deemed

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

sufficiently outstanding and pertinent to the mechanical design of the plant to be described at some length.

River-Water Intake

The intake consists of a stone and concrete structure and lagoon built at the head of Belle Isle in the Detroit River. The lagoon, intake, and river tunnel have been designed for a maximum capacity of 940 mgd, with an average flow of 700 mgd. The lagoon design was based on preliminary studies made on a model built to scale. Surveys and tests were also made in the Detroit River, with reference to pollution from Fox and Conners creeks. Low approach velocities tending to reduce troubles from frazil ice and also to produce a better supply of water were contemplated.

The lagoon has an entrance at the northeast, or upstream, end, a back channel to the south, and intake structure at the west end. The effective length of the lagoon is 2600 ft, the width about 200 ft at the mouth and 450 ft near the intake structure, and the depth about 28 ft (1, 2).[3]

Water from the lagoon is led into the intake structure through two shafts, one leading to the old 10-ft diameter river tunnel, placed in service in 1905 and the other to the new $15^1/_2$-ft diameter river tunnel about 4250 ft long terminating in the screen chamber in Water Works Park. The new tunnel was placed in service in 1931. The old brick-lined river tunnel is built in clay with its invert, i.e., the bottom inside, 66 ft below the river level; the new tunnel is concrete-lined, built in rock with its invert 181 ft below river level. An emergency water inlet from the river, independent of the lagoon, is connected to the intake structure. Emergency operation, controlled by a large float-operated poppet valve, occurs when the water level in the lagoon falls 12 or more in. below the river level.

Land Tunnels

The land tunnels, conveying water from the screen chamber in Water Works Park to Springwells Station, are about $10^1/_2$ miles long. From Water Works Park, a 14-ft diameter section extends approximately north about two miles to a junction well, where two connections are provided. One connection, 10 ft in diameter, for the future extension to the northeast, is blocked; the other ties into the 12-ft diameter section proceeding west to the Springwells Station. The tunnel, concrete-lined, was built in clay; and a large part of the work was done under compressed air. With a coefficient $C = 120$ in the Williams and Hazen formula, the tunnel capacity to the junction well is 570 mgd, and from there on, 350 mgd. The capacity of the future northeast extension is estimated at 220 mgd. The 14-ft section of the tunnel under 67 ft head of water at Water Works Park rises 25.7 ft to the junction well; the 12-ft section then declines 18.8 ft to the station. The invert of the tunnel is 93 ft below grade at the entrance to the low-lift plant (3).

Low-Lift Pumping Plant

The low-lift pumping plant, because of the depressed hydraulic grade line occasioned by the long tunnel from the river intake, required several novel features, among which were: (*a*) a deep pit for the low-lift pumps, (*b*) motor-driven centrifugal pumps in both the low-lift and high-lift plants, and (*c*) a combination of constant-speed and adjustable-speed motors of various sizes to take load fluctuations in an efficient manner. In order to appreciate the function and duty of these centrifugal pumps, as well as the reasons for selecting motor drives, a description of the hydraulic plant is given before reviewing the engineering studies made on the available pump drives.

Low-Lift Pumping-Plant Studies. The low-lift pumping plant, because of the difficult conditions already described, was the subject of intensive study. Twenty-one different schemes, all involving the use of centrifugal pumps, were investigated. The schemes are outlined below as typical examples of various methods studied to meet adverse conditions, namely, nine designs with vertical motor-driven pumps in a circular plant, four designs with horizontal motor-driven pumps, three designs with horizontal turbine-driven pumps in a circular plant, three designs of rectangular plants with both horizontal motor and turbine drive, and two special designs of cellular structures built up of independent shafts, each shaft containing a vertical motor-driven unit. The study reviewed also the problems involved in the several designs from the standpoint of construction

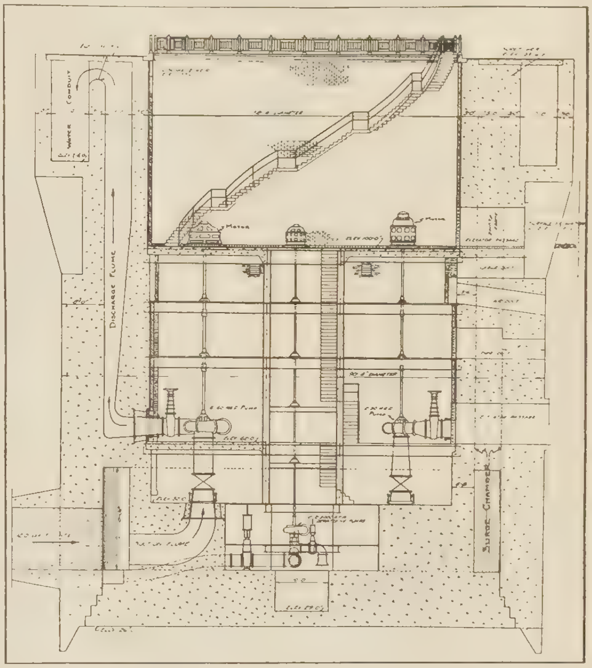

Fig. 3 Cross Section of Low-Lift Pumping Plant, Showing Location of Pumps, Discharge and Suction, and Surge Flumes

difficulties, water-surge adequacy, operating reliability, and cost.

Particular attention was given the relative reliability of the two practicable kinds of motive power, namely, steam and electricity. Because of cost, water turbines had been eliminated from consideration. The principal objections to the use of steam were that, since the turbines must be placed about 70 ft below finished grade, long vertical 8-in. feeder mains would be required for carrying 300-lb steam to the throttle; that the support of these mains introduced unusual structural problems; and that stresses arising out of pipe movement might result in joint failure. Further it was pointed out that although it is perhaps practicable to supply automatic-control equipment for the prompt closure of a broken header, the breakage of a main in a station so far below ground might result in serious injury or death to employees.

The reliability of electric motors, assuming that they were placed out of the reach of flooding, was limited only by the failure of the motors themselves or by the failure of the source of supply. The duplication of units was proposed to provide for the first contingency, and duplicate underground feeders from an adjacent power plant and a partial reserve supply from an independent source of power, for the second. The contingency of

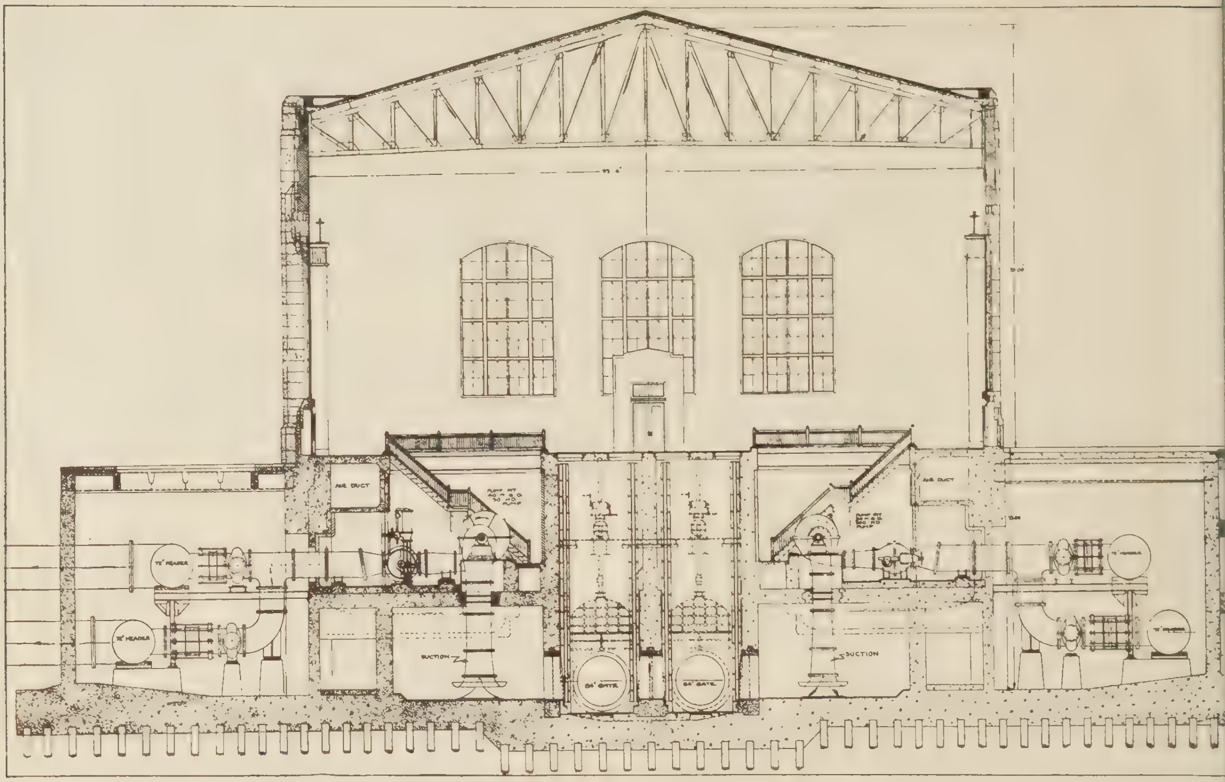

FIG. 4 CROSS SECTION OF HIGH-LIFT PUMPING PLANT, SHOWING LOCATION OF PUMPS AND PIPING

flooded motors was eliminated by the use of vertical units, with the motor floor placed above the level of the river. In the plant, as built, flooding of any sort has been reduced to the possibility of a broken pump casing, as the surge chambers are incorporated in the outside walls of the structure, and the pumps discharge up through vertical concrete conduits, also in the walls (4).

Low-Lift Pumping Plant. The low-lift pumping plant receiving river water from the tunnel previously described, is shown in cross-sectional elevation in Fig. 3. The circular well housing the pumping plant is 55 ft in diameter, and contains eight main-unit and two auxiliary motor-driven vertical centrifugal pumps. The total rated capacity of the plant is 435 mgd against a head of 50 to 60 ft. Main and auxiliary pumps are driven by motors of 750 hp, 350 hp, and 100 hp.

The pumps discharge into vertical flumes built between two concentric cylinders, with a separate flume for each main pump or eight in all. These flumes terminate in a weir, located in the top of a common conduit placed with its top at the main-floor level. Between the pump flumes there are eight open spaces running to the bottom of the substructure. These spaces serve as water-surge chambers. Since there is a weir connected to the water conduit at the top of each space, this design gives a spilling-type surge well. After the pumps were placed in service, test measurements of a surge were found to be close to predictions made from the model-test survey (5). The pumps located 40 ft below the motors driving them were so placed that the suction lift at maximum demand would not exceed a dynamic lift of 12 ft.

The pumps are equipped with hydraulically operated gate valves, controlled by electric-solenoid four-way valves. The gate valves on the discharge side are electrically interlocked with the control circuit of the motors. The control is such that while the pump can be started from the switchboard only, it can be stopped both at the switchboard or at the pumps. The two auxiliary pumps, arranged to pump from the tunnel or the low-lift pumping plant, can also pump out the tunnel for dewatering purposes.

FILTRATION PLANT

Raw water from the low-lift pumping plant flows by gravity under the turbine house to the mixing chamber, where a small amount of chlorine is added. The water prior to reaching the mixing chamber is dosed with a solution of alum and ammonium sulphate and, as this solution is added before reaching the low-lift plant pumps, these aid in the mixing process. The alum serves to coagulate and entrain the suspended matter in the water. The chlorine and ammonium sulphate form chloramines which serve to sterilize the incoming water, thereby placing less bacterial load on the plant. From the mixing chamber, the water passes to the sedimentation basin, where its detention is two hours at the normal rate of operation.

After the sedimentation the water flows to the filters where the material which was too fine to settle is removed. Sand filters which are constructed for backwashing, filter at the rate of 0.3 ft per minute. After filtration, another small quantity of chlorine is injected as the water is conveyed to storage reservoirs or to the high-lift pumping plant.

The filtration plant will ultimately consist of 68 filters of 272 mgd total capacity. Each filter has an area of 0.025 acres and is of the rapid sand type designed for an output of 4 mgd, or 160 mgd per acre per day. The filter medium consists of 20 inches of filter sand on top of 18 inches of gravel varying in size from coarse to fine.

The average amount of chemicals used for dosing is as follows: alum 100 lb per mg, ammonium 2 lb per mg, prechlorine 1.5 lb per mg, postchlorine 1.0 lb per mg.

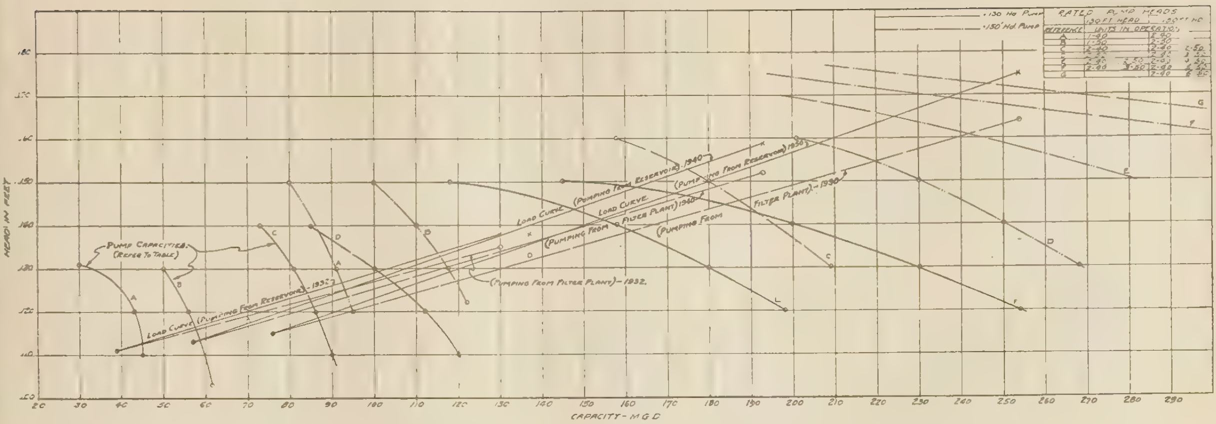

Fig. 5 Characteristic Curves for Centrifugal-Pump Output

Eventually there will be three 20-million-gallon filtered-water reservoirs amounting to 22 per cent of the maximum capacity of the filter plant. Two reservoirs of concrete construction about 20 ft deep and with an area of 3.3 acres are now in service. The mixing chamber, sedimentation basins, filters, chemical house, laboratory, and reservoirs are all grouped as a part of the filtration system.

High-Lift Pumping Plant

The high-lift or filtered-water pumping plant taking water from the filter plant or underground-reservoir storage, delivers it to the city-mains distribution system. Because of the extensive area covered by the system, it is divided into four independent zones, two high-pressure, one intermediate-pressure, and one low-pressure. Springwells Station supplies one of the high-pressure zones and, in parallel with Water Works Park Station, the intermediate-pressure zone. The low-pressure zone is served solely by Water Works Park Station. The high-lift plant accordingly operates in two sections at different pressures.

There are 16 pumps, placed in pairs in 8 pump pits, each about 18 ft deep. The present sizes are 17, 30, 40, and 50 mgd each. Ultimately the 17-mgd units will be replaced by 40- and 50-mgd units making the total installed capacity 680 mgd.

Driving the pumps are four slip-ring and twelve synchronous motors of 700 to 1725 hp. The heads pumped against are 140 and 200 ft, respectively, for the intermediate- and high-pressure zones. Each pump is connected to a double main, located in the pipe vault, through an automatic check valve and hydraulic gate valves. The six distribution mains leading from the pumping plant to the street mains are constructed of 72-in. steel pipe. All pumps are controlled from the main switchboard. Fig. 4 shows a cross section through the high-lift pumping plant, with the arrangement of the pumps and piping.

The centrifugal pumps have a steep capacity-head characteristic, but even so it was necessary to install 680 mgd capacity in order to provide for a maximum hour rate of 400 mgd, with 70 mgd in pumps in reserve capacity. Hence, it was necessary to install a rated pump capacity of over 50 per cent greater than the maximum demand. A typical characteristic-curve study for the selection of pumps to match the city-water demand is shown in Fig. 5. This figure shows the relation of the load curve, which rises as the load increases with respect to the capacity-head curve of the centrifugal pump, where decreasing capacity accompanies increased head.

Check and Gate Valves. Other features of the pumping plant which merit a short description are the check and gate valves. One of the most important functions in a pumping plant is that performed by the check valve in the discharge line of pumps. Water check valves must close quickly, without water-hammer effect, and should also be equipped to permit throttling of the flow. Eighteen automatic-type water check valves in sizes of 16 in. to 36 in. are installed. All main gate valves on the pumps are of the hydraulically operated solid-wedge disk type. The water pressure for operating the gate and check valves is 100 lb per sq in. supplied by booster pumps, storage tanks, and piping system.

2 ENGINEERING STUDIES OF PUMP DRIVES

The Springwells Station when first proposed, presented several design complications as the result of: (*a*) the necessarily depressed hydraulic grade line at the site attendant upon a long river-water tunnel, (*b*) the location with respect to the city-mains distribution system and its fluctuating water flow, and (*c*) the consideration of economy of operation and similar factors. The first problem was met as has been described by the construction of a deep-well low-lift pump plant. The second and third difficulties happily were met simultaneously by the use of motor-driven centrifugal pumps throughout the station with combinations of constant-speed and adjustable-speed motors of various sizes to accommodate efficiently the load variations. The considerations governing the selection of pumps are reviewed under the title "Relative Pumping-Equipment Costs." The sources of power supply, and electrical generating plant on the site, and partial stand-by service, are described in other sections.

Relative Pumping-Equipment Costs

Engineering studies were made on the relative construction and operating costs of the plant. At the outset, the following types of drive for centrifugal pumps were considered:

1 Steam-turbine drive through helical reduction gears
2 Variable-speed electric drive with
   (*a*) A combination of constant- and adjustable-speed motors
   (*b*) Slip-ring type motors.
3 Constant-speed electric drive, with
   (*a*) Synchronous motors
   (*b*) Squirrel-cage motors.

Preliminary studies based on available cost data and load-duration data led to the following conclusions: (*a*) The total investment required for each type of motor drive is less than for turbine drive; (*b*) the annual costs for fuel, maintenance, and labor is less for motor drive than for steam-turbine drive; (*c*) the reliability afforded by motor drive is at least equal to that of turbine drive. This particular conclusion was premised

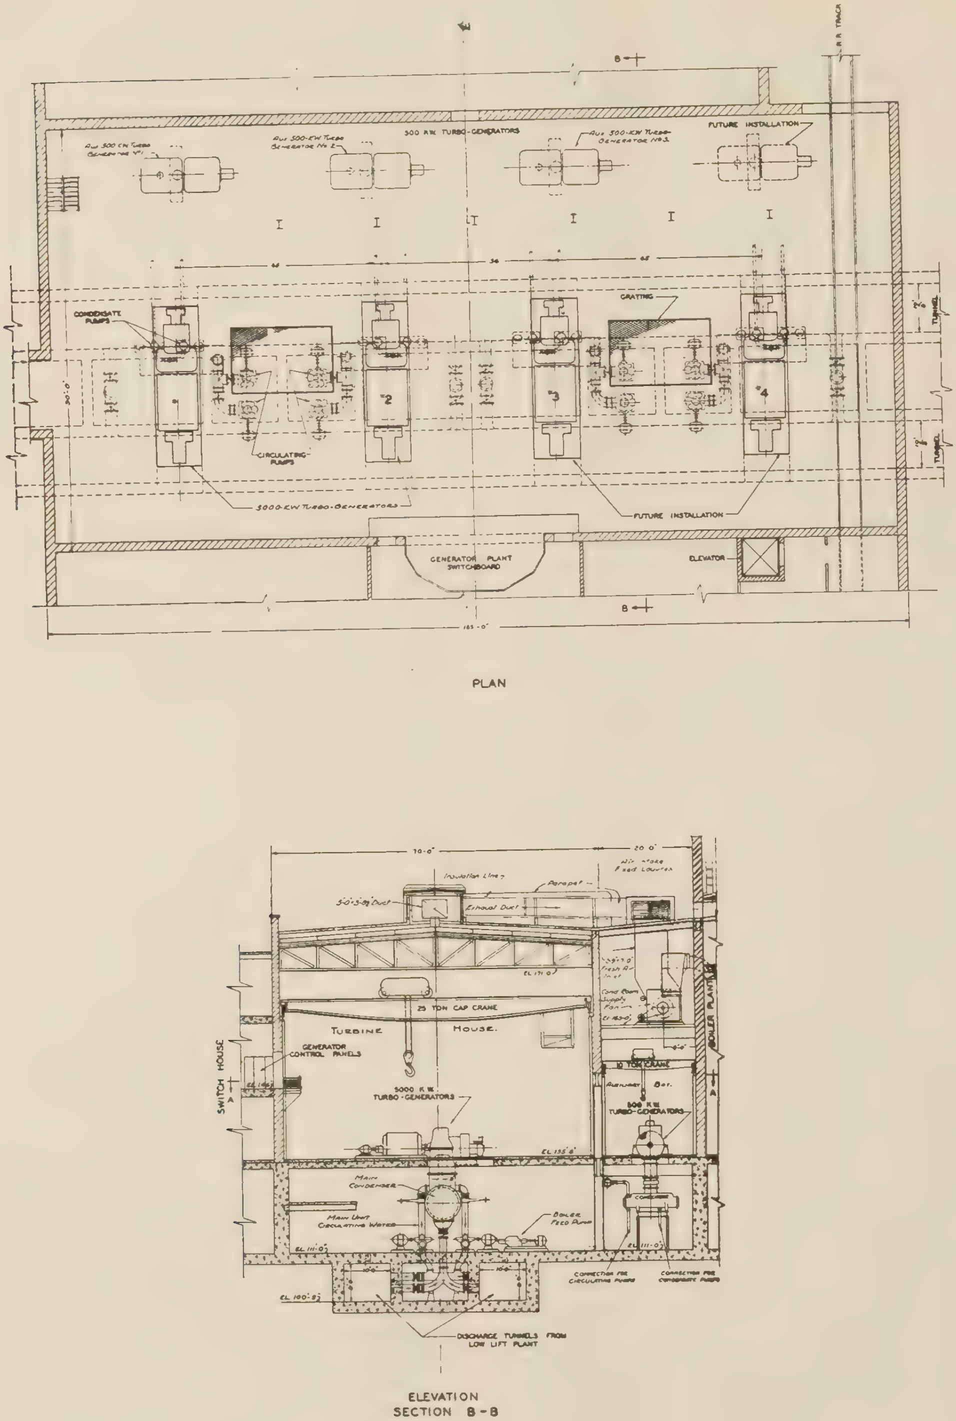

Fig. 6 Plan and Elevation of the Turbine House, Showing Main and Auxiliary Turbogenerators, Condensers, and Piping

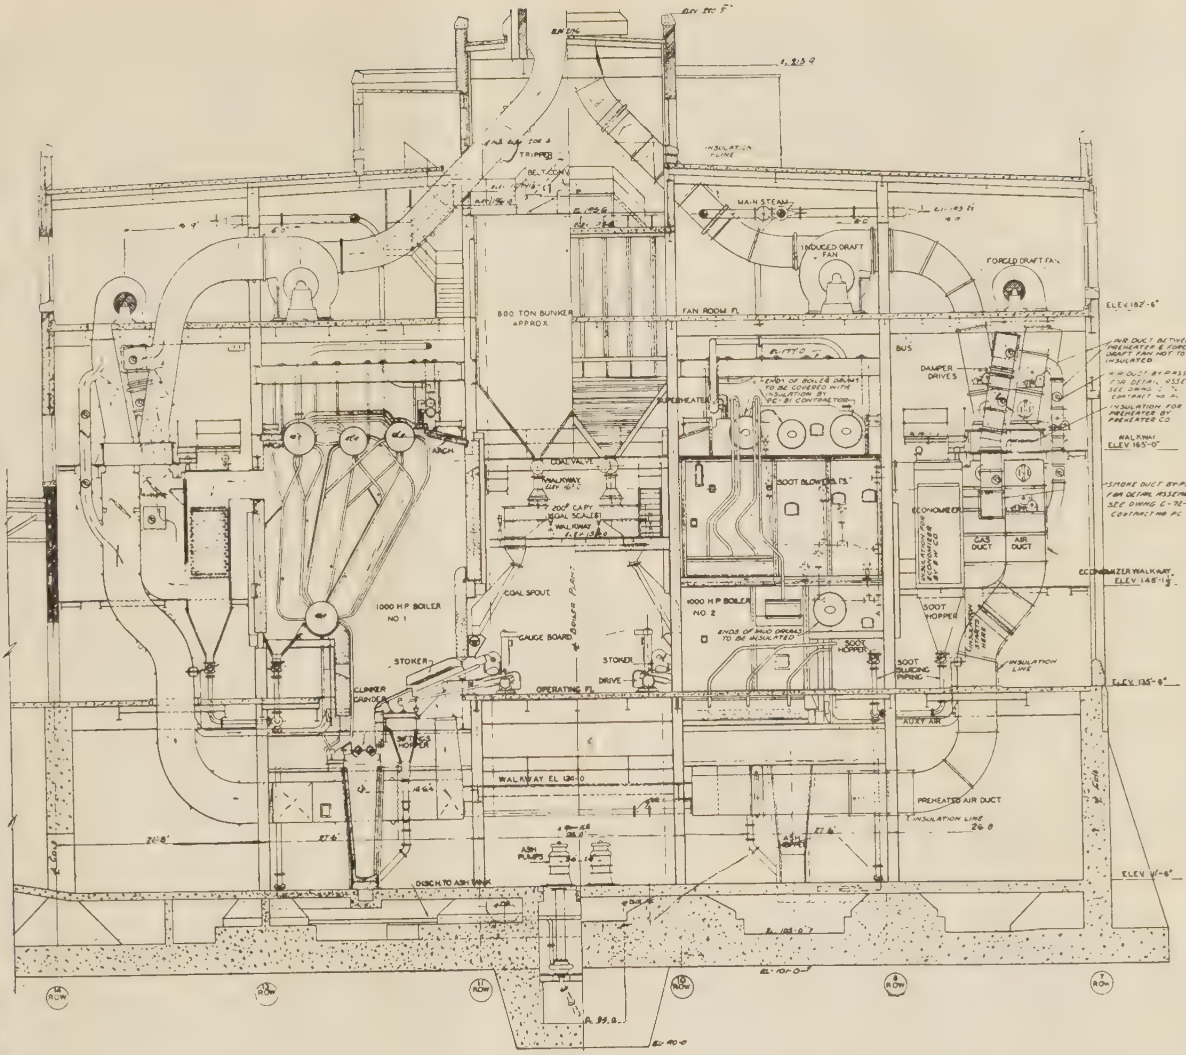

Fig. 7 Cross Section of Boilerhouse, Showing Design of Major Units of Steam-Generating Equipment

on the installation on the site, of turbogenerators having a capacity equal to the maximum hour capacity and a stand-by transformer installation equal to the capacity of one turbogenerator, to permit shutting down for overhaul; (*d*) capacity and head regulation adequate for conditions of minimum, average, and maximum demand can be obtained by providing one or two variable-speed slip-ring motors in each service.

The final engineering study was reduced to four schemes, namely:

1 Alternating-current motor drive for all main pumping units, embodying a combination of constant-speed, synchronous, and variable-speed slip-ring motors.

2 Steam-turbine drive for all high-lift pumps and d-c motor drive for all low-lift pumps.

3 Steam-turbine drive throughout.

4 Steam-turbine drive in the high-lift plant and water-turbine drive in the low-lift plant.

The comparative estimates are summarized in Table 1. The figures, although comparable, are not complete as they do not include those costs common to all schemes.

TABLE 1 COMPARATIVE COST ESTIMATES FOR PUMPING STATIONS AND EQUIPMENT OF ITEMS NOT COMMON TO ALL SCHEMES

Plan	Construction cost	Annual operating cost
Alternating-current motors throughout	$2,316,560	$588,160
Steam turbines in high lift and d-c motors in low lift	2,537,050	638,470
Steam turbines throughout	2,319,050	619,630
Steam turbines in high lift and water turbines in low lift	2,559,360	662,110

On the basis, therefore, of a lower cost in the plant as a whole, and of greater reliability in the low-lift plant, motor equipment throughout, with an adjoining steam-electric generating plant, was adopted by the Board of Water Commissioners (6, 7).

Precedents for Pumping Equipment

Prior to 1923, all water pumping in Detroit had been done with plunger pumps, driven by reciprocating steam engines. The original installation at Water Works Park, consisting of one compound pump with a capacity of 24 mgd, was put into service in 1877. Then, during the following 46 years, 10 triple-expansion and two compound engines, with capacities of 25 to 37 mgd

were installed. In the year 1924 there was installed in this station a total capacity of 378 mgd in steam pumping engines.

It is of interest to note that, although the policy of the Water Department until 1924 was to distribute water with triple-expansion engines, since that time all new units, including all of the new Springwells plant, have been motor-driven centrifugal pumps.

3 POWER PLANT

The necessity for insuring absolute continuity of service prompted the choice of an electric power-generating plant on the Springwells site rather than dependence wholly on transmission lines from outside supply, even if available from two independent sources. Limited throw-over service has been provided for reserve capacity, however, to the extent of one main unit. The power-plant design was based on generating 95 per cent of the power requirement and purchasing the remainder from a central-station source. It was estimated that water pumpage would require 4000 kw per 100 mgd or about 96,000 kwhr daily.

The initial installation consists of two 5000-kw main and three 500-kw auxiliary turbogenerators with a 5000-kw stand-by transformer bank connected to the Public Lighting Commission's system to provide an emergency supply from an outside source. This capacity is sufficient for a maximum hourly pumping rate corresponding to 275 mgd or 11,400,000 gal of water per hr. The steam-generating equipment includes two boiler units each with a maximum output of 90,000 lb of steam per hr.

The ultimate installation will consist of four 5000-kw main units, four 500-kw auxiliary turbogenerators, and four 90,000-lb per hr boilers. The stand-by connection of 5000 kw will, of course, be retained. The ultimate plant is designed to match the maximum hourly pumping rate corresponding to 550 mgd or 22,800,000 gal of water per hr. A cross-sectional elevation of the powerhouse is shown in Figs. 6 and 7.

Turbogenerators

The main steam turbines are 15-stage, 3600-rpm machines, designed for operation at 350 lb gage steam pressure, 700 F temperature, and condensing operation at a back pressure of $1^1/_2$ in. mercury. The generators rated at 5000 kw, at 80 per cent power factor, are 4600-volt, 3-phase, 60-cycle. The turbines are equipped with bleed points at the ninth and twelfth stages for extraction-steam feedwater heating.

The auxiliary turbogenerators are 6-stage, 500-kw at 80 percent power factor, 460-volt, 3-phase machines, with condensers. The turbines are of special bleeder type to supply building-heating requirements.

Condensing Water

The condensing water for the condensers is taken from one of the two raw-water tunnels passing through the condenser room as shown in Fig. 2. The water is drawn through the main-unit 10,000-sq ft surface condensers by means of two 4000-gpm, $13^1/_2$-ft head, d-c-motor-driven centrifugal pumps. Because of conditions requiring the condensers to be below water level, the pumps need to overcome friction and velocity-change losses only. The 800-sq ft condensers for the auxiliary turbines are supplied from an auxiliary tunnel connected to the main raw-water tunnels. Each machine has one condensing-water pump, driven by a d-c motor. Since the amount of condensing water is small compared with the quantity of raw water being pumped, the increase in raw-water temperature is negligible.

Power-Plant Auxiliaries

After an extended study of the various types and methods of operating power-plant auxiliaries, it was decided to provide the power plant with 240-volt, d-c motor-driven auxiliaries, with adjustable speed control for each motor using a heavy-duty drum-type controller, mounted in a steel cubicle with a carbon circuit breaker, ammeter, and related equipment. Power is supplied through an open-type ring bus made up of three $4 \times {}^1/_4$-in. copper bars making a complete circuit of the turbine room and boilerhouse. The 240-volt direct current is supplied by three 400-kw motor-generator sets, operated on 460-volt, 3-phase power from the 500-kw turbogenerators.

The power-plant auxiliaries are entirely separated from the auxiliary-power equipment of the pumping and filtration plants, where 440-volt, 3-phase a-c motor-driven auxiliaries are used.

Stand-by Power Supply

The power plant was designed to have a central-station feeder with a capacity equal to one main turbogenerator to meet emergency requirements, such as loss of one of the generators during peak loads. Hence, it was not necessary to provide reserve capacity in main turbogenerators and boilers.

The central-station feeder is a 24,000-volt line from the Public Lighting Commission's system, which has an 80,000-kw steam-generating plant about five miles from the Springwells Station. This feeder is connected to a 5000-kw, 80 per cent power factor, 24,000/4600-volt power transformer. The service is used continuously at a very low load, about 100 kw, and is ready for stand-by service up to a demand of 5000 kw. The Springwells generators are operated in synchronism with the P.L.C. power system.

Electrical System

The electric-power system was designed for 4600-volt, 60-cycle, 3-phase alternating current for the main units; 460-volt, 60-cycle 3-phase power for the auxiliary units; 240-volt d-c power for the power-plant auxiliaries; 220-volt d-c power for the exciters of the synchronous motors of the main pumps; 125-volt power from storage batteries for operation of oil circuit breakers and emergency lighting system; 110/220-volt, 3-wire, a-c lighting system and 18-volt power from storage battery for operation of the switchboard signal system.

The 4600-volt switchgear is of the metal-clad oil-circuit-breaker vertical-lift, heavy-duty type. The bus is arranged in five parts, one for each main turbogenerator plus a synchronizing bus that is connected to the generator bus sections through bustie reactors.

The main switchgear and bus system required much study from the standpoint of (*a*) the size and current-interrupting capacity of the oil circuit breakers, (*b*) the surges caused by starting motors on large centrifugal pumps, (*c*) the central-station feeder, and (*d*) the operating problems with 5000-kw turbogenerators in synchronism with a central-station power system.

The 460-volt switchgear is of the oil-circuit-breaker, metal-cubicle type. The bus is in duplicate so that each feeder may be supplied by either bus.

There are three separate storage batteries, each complete with its battery-charging motor-generator sets. There are two 60-cell storage batteries for 125-volt service, one for operating solenoids on the oil circuit breakers and the other for the emergency lighting service throughout the various buildings. The third storage battery is of the 8-cell, 18-volt type, for operation of signal and instrument lights on the switchboards in the pumping and power plants.

Steam Generation

Each steam-generating unit includes a boiler, and underfeed stoker, superheater, air heater, economizer, and a forced-draft

and an induced-draft fan. The 4-drum bent-tube boiler is designed for 380-lb pressure and a normal output of 70,000 lb of steam per hr. Provision is made for a maximum evaporation up to 90,000 lb per hr. The side and bridge walls of the 4125-cu ft combustion chamber are lined with $3^1/_4$-in. OD No. 7 Bwg plain water-cooled tubes. The total radiant and convection heating surface amounts to 10,898 sq ft per boiler.

A convection superheater of 1740 sq ft is located in the first gas pass to receive a portion of radiant heat at low rating and accordingly to minimize the range of superheated-steam temperature variation. At the maximum rating the guaranteed steam temperature is 715 F.

The economizer surface amounting to 2673 sq ft per unit is installed. It consists of 2-in. OD plain tubes stacked 22 tubes high and 16 tubes wide, joined by wrought-steel return bends.

The air heater which is of the mechanical regenerative rotating type has an active heating surface of approximately 9500 sq ft and supplies air to the fuel bed at temperatures up to 300 F.

The underfeed stoker for each boiler unit has 8 retorts each with 31 standard-thickness tuyères and a 4-row undulating-link extension grate. The total projected area of each stoker is 195 sq ft. Each stoker is guaranteed to burn 8900 lb per hr of 13,500-Btu coal and 11,000 lb per hr of 12,000-Btu coal. The stoker is driven through a crankshaft by a d-c motor with a drum-type manually operated controller. The clinker grinder is separately operated by a manually controlled d-c motor.

A steam-generating unit includes one induced- and one forced-draft fan separately driven by adjustable-speed d-c motors. The fans, located on the top floor of the boilerhouse, are designed for starting and stopping at that point. Speed is remotely controlled from the boiler-operating board located on the main floor of the boiler room near the stoker. The forced-draft fan is designed for a maximum capacity of 45,000 cu ft per min of air at 70 F, against a static pressure of 13.5 in. of water. The induced-draft fan is rated at a maximum capacity of 75,000 cu ft per min of flue gas at 300 F, against a static-pressure differential of 11.0 in. of water.

In front of each boiler is a control panel on which are mounted the operating instruments such as steam-flow air-flow meter, draft gages, CO_2 meter, pressure gages, temperature instruments, and controls for forced- and induced-draft fans, stokers, dampers, and related items.

Piping System. The superheated-steam piping system is arranged as a loop header at the top floor of the boilerhouse with two 8-in. supply feeders leading to the basement of the turbine house where there is another 10-in. pipe loop-header system which connects with the feeders for each main and auxiliary turbine. The piping is laid out and all necessary sectionalizing valves are installed so that additional changes will not be necessary when future turbines and boilers are installed.

There are also two 4-in. saturated-steam headers connected to each boiler and leading to duplicate pressure-reducing stations, where steam is reduced from 380 to 200 lb per sq in. Duplicate 200-lb pressure lines convey steam to feeder lines for auxiliaries such as soot blowers and air ejectors. The 200-lb pressure line is connected to a second reducing station to provide a 3 to 8-lb emergency steam supply for building heating.

Feedwater Cycle. Condensate from the auxiliary units and building-heating returns are injected into the main-unit condensers for deaeration before returning to the feedwater system. Duplicate hotwell pumps of 250 gpm and 200-ft head driven by d-c motors, discharge condensate through two stages of feedwater heating to the suction of the boiler feed pump at approximately 40 lb pressure. Make-up water amounting to $1^1/_2$ per cent of the total boiler feed is evaporated in an evaporator that is supplied with steam from the ninth-stage extraction line of each main turbine.

There are two feedwater-storage tanks of the open type filled with distilled water to meet emergencies and fluctuations in condensate demand attendant upon load changes. Storage-tank water is discharged to the main condensers to be deaerated before entering the boiler feed system.

Condensate in the main condenser is maintained at a predetermined level by two float valves, one of which is set higher than the other. The hotwell-pump supply of condensate to match the demand for boiler feed is thus insured. Any excess condensate is pumped through one float-operated valve to the storage tanks. In case of a deficiency, water is fed back to the main condenser from the storage tanks through the other float-operated valve.

The design provides for an ultimate installation of five boiler feed pumps, two to be steam-turbine driven and three d-c-motor driven. For the present installation three six-stage centrifugal pumps have been provided, each of 300-gal-per-min capacity at 1050 ft head, to deliver feedwater at a temperature of 275 F to the economizers, and thence into the boilers. One of these pumps is driven by a steam turbine and two by d-c motors.

Building Heating. The heating system for the buildings, designed for a steam demand in zero weather of 25,000 lb per hr, normally is supplied by bleeding steam from the auxiliary turbines at gage pressures of 2 to 5 lb. The heating-system condensate is returned under vacuum to the main-turbine condensers for deaeration. Before reaching the condenser, the heating returns pass through a heat exchanger to transfer some heat to the feedwater.

Coal Handling. An outside coal-storage capacity of 18,000 tons is provided to which coal is brought by means of railroad cars or motor trucks. Coal is unloaded directly into a track hopper and conveyed to coal bunkers or placed in the coal-storage pit. Handling from the outside storage pit to a reclaiming hopper is by means of a motor-operated 2-cu yd dragline scraper capable of handling 75 tons of coal per hr. From the reclaiming hopper, the coal is carried on an apron conveyor conveying it to a crusher in which the lumps up to 24 in. in size are crushed to a final product not exceeding $^3/_4$ in. in size. From the crusher the coal is raised by a bucket elevator to a 100-ton per hr belt conveyor from which it can be distributed to the bunkers or by-passed to a chute for outside coal storage.

Ash Handling. Refuse from the boilers, after passing through the clinker grinders, drops into an ash hopper directly underneath. From the ash hopper cinders are handled through sluiceways into a water-filled ash-pump pit from which the refuse mixed with water is pumped to an overhead ash-storage tank by means of two centrifugal pumps. Cinders are removed from the ash-storage tank by dumping into motor trucks.

Summary of Power-Plant Features

In concluding this section on the power-plant design, there are certain unusual features that should be emphasized. For example, the combination pumping and power plants were designed for a four-step power-conversion plant (coal, steam, electricity, mechanical power), whereas nearly all other steam-operated water-works plants are of the three-step power plan (coal, steam, mechanical work) (8). The use of reasonably high steam pressures and temperatures (380 lb, 715 F) was also of marked interest. There were many features that received special study, prior to making decisions, such as type and size of electrical switchgear, size of turbines and boiler units, type of stokers, building heating, feedwater cycle, and coal and ash-handling systems.

4 EXPECTED PERFORMANCE GUARANTEES, AND ACCEPTANCE TESTS

In preparing plans, specifications, and contracts for securing plant equipment, operating schedules were prepared and from these, estimates were made on expected performance of equipment. Bids were obtained based on guaranteed results with penalty and bonus clauses in the contract. This feature is an important phase of purchasing major equipment for a municipal project in that the city charter of Detroit requires that contracts be awarded to the lowest responsible bidder. The bids were evaluated, based on contract cost, plus the power-operating costs over a 20-year period, with such items as interest, cost of power, hours of operation, and similar items taken into account. The contracts were awarded on the basis of the lowest evaluated bid, where the bidder complied with all requirements of the specifications, with the understanding that field tests were to be performed and a bonus or penalty applied to the contract, depending on whether the field tests showed better or poorer performances than those guaranteed by the bidder.

The contracts for the major pumping equipment required that the contractor construct and test to the satisfaction of the water department, a model pump or pumps. These models were used and from the test results obtained on them, there was calculated the expected performance that would apply to the full-sized pumps. The latter were constructed in direct ratio to the size of the model pump as to design of all parts of the pumps. The results obtained through designing from model-pump tests have been most satisfactory. One of the reasons for having model pumps constructed is that pump manufacturers are unable to test large pumps in their shops. Further, model pumps offer the manufacturers economical means of altering pump designs which would not otherwise be practicable in constructing large pumps. By making proper allowances for ratio factors, the model-pump test is considered equal to tests on full-sized pumps.

Since design and cost data are technically open to public inspection, contract prices, bonuses, and penalties are given in this paper. Reviews are outlined on the acceptance tests on (*a*) the hydraulic pumps in the low- and high-lift pumping plants, (*b*) the turbogenerators, and (*c*) the steam-generating equipment.

Acceptance Tests of Hydraulic Pumps

Field acceptance tests were made after the equipment had been installed and operated.

The field test methods and results are described in the following sections.

Pump-Test Methods. Heads were measured by means of mercury manometers and piezometer on the suction and discharge flanges of the pumps. Capacities were measured by means of a manometer connected to large venturi tubes. The specific gravity of the manometer fluids varied from about 1.25 to 2.8 depending upon the size of the venturi tube and the flow to be measured. Power input to the motors was measured with an indicating polyphase wattmeter and checked with a rotating standard.

The test procedure followed as nearly as possible the A.S.M.E. Power Test Code. Each pump in the low-lift and high-lift plants was tested over the operating range of heads and a separate test curve was plotted. In general, the duration of each test was for a period of twenty minutes with sufficient time interval at each test load to allow stabilization of the new load. Changes of load were accomplished by throttling the discharge or check valves of the pumps.

The determination of heads on the low-lift pumps was especially difficult because of the low head range of these pumps (40 to 70 ft total dynamic head). A pressure-equalizing ring encircling the suction and discharge flange and connected at the quarter points of the pipe was installed on all pumps, and the head-measuring manometers were connected to the pressure rings.

A manometer or U tube was used to measure the discharge heads on the high-lift pumps. The open end extended about 18 ft from the floor of the pump pit.

Discussion of Pump-Test Results. When the preliminary tests on the low-lift pumps indicated that the performance of several pumps was below guaranteed conditions, the contractor was allowed to replace three impellers and to work on other impellers in order to increase efficiencies and more nearly meet guaranteed capacities. A summary of the average overall weighted test efficiencies with bonus and penalty amounts appears in Table 2.

The field tests on the pumps showed that they varied from the predicted results, obtained from the tests on the model pumps, from 3 per cent below to 1 per cent above the overall weighted efficiencies, while the field-test efficiencies varied from 0.75 per cent below to $3^1/_2$ per cent above the guaranteed efficiencies. The bonus anticipated by the pump contractor was less than indicated from model-pump-test results. Nearly all the

pumps were overcapacity, which was remedied on some of the pumps.

The idea of pump testing in the field, its advantages and disadvantages, has been under active discussion for some time. It has been borne out in this case that it is to the purchasers' advantage, especially where bonus and penalty contracts apply, to have acceptance tests made in the field, but it is also to the mutual advantage of the purchaser and manufacturer to have shop tests made on pumps prior to shipment, either model-pump tests or tests on the full-sized pumps.

Turbogenerator Acceptance Tests

The contracts for turbogenerators included a bonus and penalty clause establishing a value of $20 per lb of weighted steam flow per hr. The manufacturer guaranteed the turbogenerators at the various loads set up in the contract (a definite weight factor to be used in averaging was established for each load) for both extracting and condensing operation, although the contract specified that field tests were to be made with full condensing operation.

Before testing operations began the units had operated longer than had been anticipated and therefore each machine was opened and cleaned thoroughly in preparation for test. In so far as possible, the test methods used conformed to the A.S.M.E. Power Test Code. Condensate was weighed with 10,000-lb test weigh scales. Initial steam temperature was measured with mercury-in-glass thermometers calibrated for full immersion and calibrated thermocouples. Initial steam pressure was measured with dead-weight gages and checked by Bourdon pressure gages, graduated in 2-lb divisions. The electric-power output of the generator was measured by means of two single-phase indicating wattmeters. Condenser leakage was measured with a dionic water tester. Corrections were applied to the field results for condenser leakage, throttle steam pressure, temperature, and back pressure.

A back pressure of $1^1/_2$ in. abs was maintained constant by a bleeder valve connected to the condenser and a direct-reading back-pressure gage. Back pressure was measured by difference between a mercurial barometer and two specially built mercury-column vacuum gages. Each of these instruments could be read to 0.01 in. of mercury. The tubes of the vacuum gages were of large bore to eliminate the need of correction for capillarity.

All instruments were calibrated before and after the tests.

In order to indicate clearly the method of evaluating the weighted steam flow and the application of the bonus and penalty system, Table 3 is included to show the guarantee on the 5000-kw turbogenerators.

TABLE 3 SUMMARY OF GUARANTEED WEIGHTED STEAM FLOW FOR ONE 5000-KW TURBOGENERATOR

Load kw	Power factor	Total steam flow, lb hr	Weight factor	Weighted steam flow, lb hr	Steam rate, lb-kwhr
2500	0.8	26,900	0.05	1345.0	10.76
3000	0.8	31,410	0.05	1570.5	10.47
3500	0.8	35,945	0.10	3594.5	10.27
4000	0.8	40,560	0.20	8112.0	10.14
4500	0.8	45,135	0.20	9027.0	10.03
5000	0.8	49,800	0.25	12450.0	9.96
5500	0.88	54,725	0.10	5472.5	9.95
6250	1.00	62,500	0.05	3125.0	10.0
Guaranteed weighted steam flow				44,696.5	

The values which are given in Table 3 are based on straight condensing operation with steam at a pressure of 350 lb per sq in. gage and with a temperature of 700 F at the turbine throttle and against a back pressure of $1^1/_2$ in. mercury.

[a] Figures given for two 500-kw turbines only. Test on third machine not completed.

Results of Turbogenerator Tests

The turbogenerators were delivered and erected in the years 1931 and 1932. However, due to the effects of the depression they were not operated until February, 1935, and field tests were not begun until October 30, 1935, although during the time the turbines were idle the internal parts were slushed with a protective coating, and the buildings were heated in winter.

The A.S.M.E. Power Test Code states that "the turbine must be in commercial operating condition." Since this applies to cleanliness, it is thought it should be more specific as this can be a serious point of contention between the owner and the manufacturer. Inasmuch as dirty blading can affect the performance of a turbine considerably, the owner has a legitimate right to insist that the turbine be tested in a normally clean condition so that test results will conform more closely to operating conditions. The manufacturer will probably insist that the turbine be tested in a factory-clean condition, which is not possible to attain in the field, even after a few days' operation.

The field-test results on the turbines are given in Table 4.

Boiler Acceptance Tests

The specifications for boiler-plant equipment stated that acceptance tests were to be made on all equipment by the Department of Water Supply in the presence of manufacturers' representatives. Due to a variety of conditions, the boilers were in operation approximately seventeen months before acceptance tests were conducted. In so far as practicable, the test methods conformed with the A.S.M.E. Boiler Test Code. The most unusual departure from the A.S.M.E. Code concerned the determination of feedwater quantity. The plant is not equipped to weigh feedwater although test weigh scales are provided for the weighing of condensate for turbine testing. A mechanical-type flow meter connected to a six-inch venturi tube in the boiler feed line was used to measure the feedwater. This meter was calibrated by means of the test weigh scales before and after the tests. Coal was weighed on automatic coal scales, which were calibrated with test weights. The various gas and air temperatures were measured with iron-constantan thermocouples connected through a selector switch to a potentiometer pyrometer. The temperature of superheated steam was measured by both a thermocouple and a mercury-in-glass thermometer. Refuse was not weighed but samples were collected and analyzed for contained combustible matter. The quantity of refuse was estimated by the A.S.M.E. formula. Flue-gas samples were drawn from three points in the duct at each sampling point and led to a combination mixing and bubbling jar by means of an air-operated aspirator. Adjustments in gas flow in the three sampling lines were controlled by pinch cocks to divide the flow equally. Orsats were of both the metal and glass types. Fuel was sampled at the stoker hopper and analyzed several times during each test for moisture content. The distillation method was used for moisture determination. After each test the total collected coal sample was reduced and sent to the laboratory for analysis.

The coal used for boiler tests was from the Pittsburgh seam in western Pennsylvania. This is a low-sulphur semicaking type coal. The average proximate analysis of the coal used for all boiler tests was as follows:

Moisture	3.03 per cent (as fired)
Volatile matter	32.38 per cent (dry basis)
Fixed carbon	60.88 per cent (dry basis)
Ash	6.74 per cent (dry basis)

Heating value, Btu per lb (dry basis)—14,040.

Results of Tests on Steam-Generating Equipment

The results of the boiler tests conformed satisfactorily with the guaranteed values. It is believed that slightly better efficiencies could be obtained under ideal conditions of operation; the values of CO_2 in the flue gas during boiler tests were slightly lower than is ordinarily obtained in normal operation. This was mostly due to the slightly inferior burning characteristics of the coal used for boiler tests. The losses unaccounted for varied from 3.19 to 7.54 per cent. The higher value corresponds to the low boiler rating (less than 30,000 lb of steam per hr) and an intermediate value of 3.29 per cent corresponds to load of 56,000 lb of steam per hr.

The guaranteed and test results of the steam-generating equipment are given in Table 5.

The estimated design heat balance, based on average winter-season load for the year 1950, indicated a steam-boiler generating unit overall efficiency of approximately 83 per cent and a resulting annual heat rate of the power plant in "coal to switchboard," of approximately 18,100 Btu per net kwhr.

The average annual expected heat-rate results of the ultimate plant are as follows:

Coal, lb per kwhr (13,500 Btu per lb)	1.34
Thermal efficiency of the power plant, per cent	18.85
Thermal efficiency of the pumping plant, per cent	14.5
Annual heat rate of power plant, Btu per kwhr	18,100
Electric power, kwhr per whphr	1.01
Coal required to pump 1,000,000 gallons of water 100 feet high, lb	570

5 OPERATION AND COMPARISON OF OPERATING RESULTS WITH ACCEPTANCE TESTS

Construction work for the entire station was practically complete except for the power plant at the end of 1932. Although the pumping plants and the filtration plant were placed on part-time operation in 1931, the city's financial difficulties together with the lower load on the system because of the depression delayed the final completion of construction and arrangements for placing the station on a twenty-four hour per day basis until 1935.

During the period of inactivity, or rather, throughout 1933 and 1934, a small group of employees now in the operating division was engaged in making trial operations of all equipment in the pumping plants and in conducting and making up reports on acceptance tests of the equipment. This work included tests of each individual pumping unit in the low- and high-lift pumping plants.

Pumping Plants

The average daily pumpage by the high-lift pumping plant during the fiscal year ending June 30, 1936, was 112.3 million

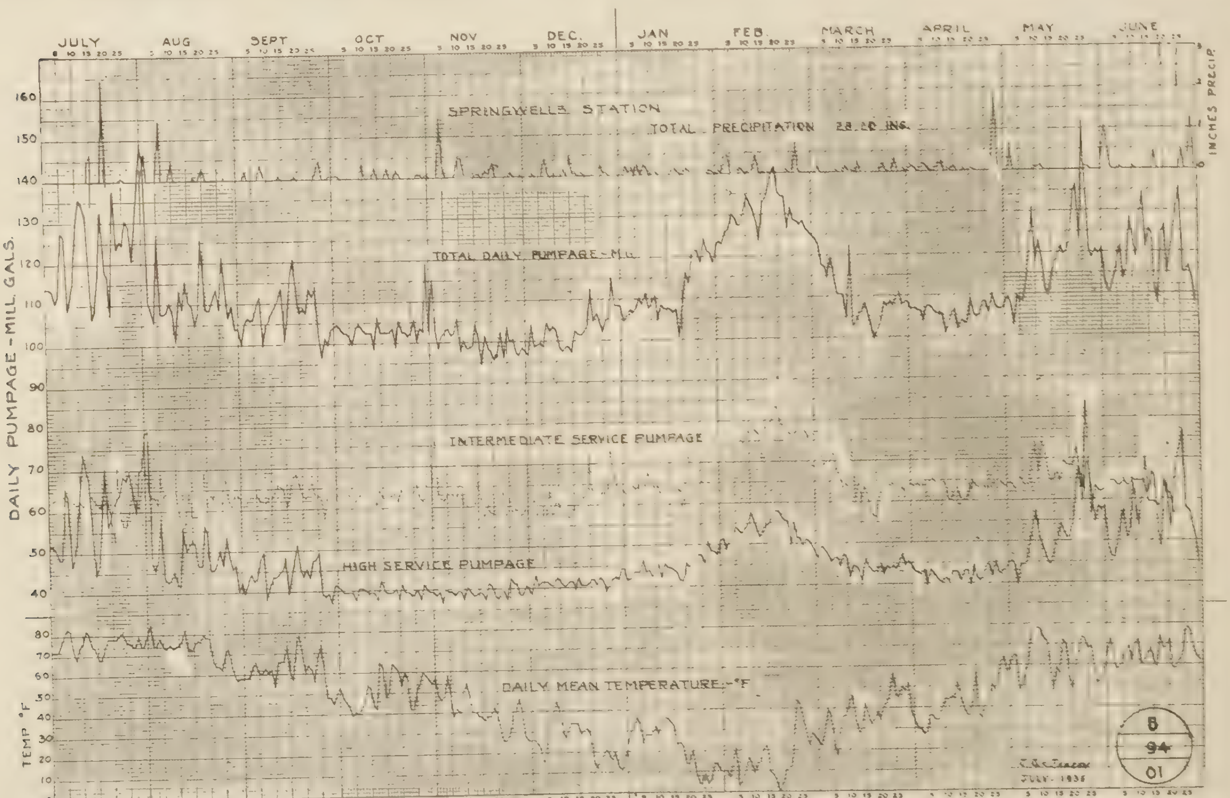

Fig. 8 Pumpage Curves

(These curves show the variation in daily pumpage throughout a year. Curves of daily mean temperature and daily precipitation are included to show how these factors affect water demand.)

gallons with a maximum day of 151.8 million gallons and a maximum hourly rate of 250 mgd. Of the two pressure systems into which this plant delivers, one designated as "intermediate system" is supplied jointly by Springwells and Water Works Park Stations. A fairly constant amount of this load is taken by Springwells with good load factor, while the other station takes the major portion of the load variations. The other pressure system designated as "high service" is a separate distribution system almost entirely residential in which the demand varies greatly throughout any one day. The minimum pumpage rate in early morning hours in this system is regularly as low as 20 mgd while maximum-demand rates have been recorded as high as 190 mgd in early evening hours in summer when lawn sprinkling prevails. This results in a poor load factor for this system, as shown in Figs. 8 and 9.

The daily pumpage by the low-lift plant is usually nearly equal to the total delivery from the high-lift plant, plus about four per cent used for washing filters. In the operation of this

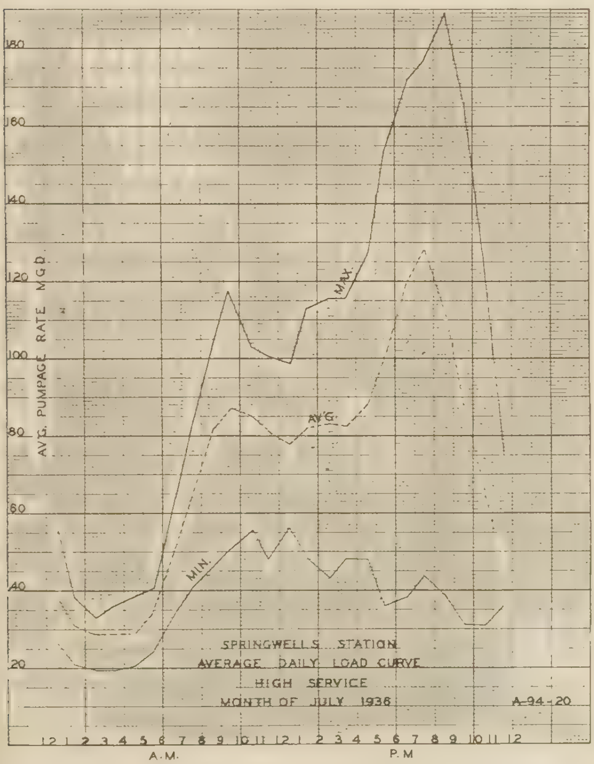

FIG. 9 LOAD CURVE

(This is an average daily-load curve for the high service system for a warm summer month. The high peak load between 8:00 and 9:00 p.m. is due to the demand for lawn sprinkling.)

plant, an attempt is made to keep the delivery at a constant rate to the filters throughout the 24 hours of any one day and variations in the high-lift plant delivery are cared for by the automatic delivery of filtered water to or withdrawal from the 40,000,000-gallon storage reservoirs. Constant delivery to the filters affords favorable conditions for coagulation and filtration and tends to reduce the cost of chemicals to a minimum, but on the other hand, reduces the amount of storage water in the reservoirs to a minimum when the distribution-system demand is at a maximum.

The low-lift pumps draw from the supply tunnel and deliver raw water over the weirs at constant elevation. Variation in head depends on the rate at which the plant is operating. The suction level is drawn lower as the rate increases. At present output, the total dynamic head on the pumps averages 46 to 47 ft and the average overall efficiency from operating records is about 76 per cent, which checks very closely with the comparative acceptance-test efficiencies.

For the fiscal year ending June 30, 1936, the average plant capacity factor was 26.3 per cent with average load factor of 75.8 per cent.

In the 72-in. steel distribution mains there are installed in the station grounds in locations best suited for accurate flow measurement, six $73^1/_4 \times 33$-in. venturi tubes. Mechanical-type flow meters connected to these venturi tubes are installed in the pumping plant in convenient locations.

Pressure in the distribution systems is held within prescribed limits at selected points remote from the pumping plant. A long-distance pressure gage for each pressure system has been installed at a distance of four and one-half miles from the plant. A sending element at the distant point actuates receiving indicators and recorders at convenient locations in the plant. These gages are electrical and the sending and receiving elements are connected by telephone lines.

From acceptance-test curves of low- and high-lift plant pump units there have been developed economy curves to assist the operators in selecting combinations of units to deliver water at the lowest possible cost. These curves Figs. 10 and 11, show that, for all units in both pumping plants, the lowest cost of delivery through pressure ranges prescribed is always at the lowest head which will give satisfactory service. Best economy is secured at the lowest possible total head on pumps regardless of the fact that the efficiency may be much below the maximum that would be secured with the units operating at higher or rated heads.

If care is exercised by operators in making proper selection of pump combinations for existing and predicted loads, it has been determined from economy curves that one million gallons of water can be delivered with power input to motors as follows:

Low-lift plant, kwhr	190
High-lift-intermediate system, kwhr	486
High-lift high-service system, kwhr	735

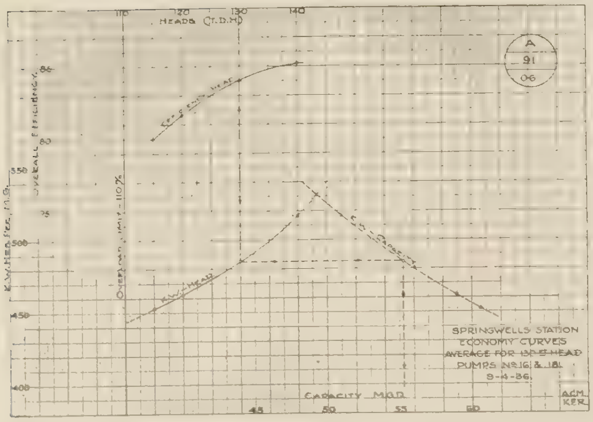

Fig. 10 Economy Curves

(Economy curves for two pumps rated at 50 mgd, 130 ft head. The two curves on the left show cost in kilowatthours per million gallons and efficiency, both plotted against head. The curves on the right show the relation between cost and capacity.)

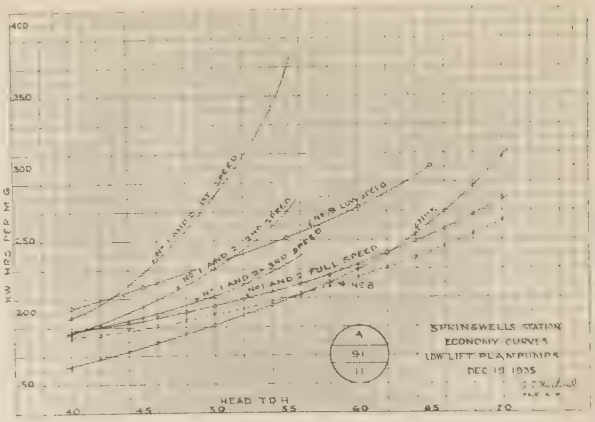

Fig. 11 Economy Curves

(These curves show the relation between total dynamic pumping head and cost of power, in terms of kilowatthours per million gallons, for all of the main pumping units in the low-lift plant.)

The average overall operating efficiency of the high-service system determined from operating records for the fiscal year ending June 30, 1936, was 85.16 per cent. From acceptance tests the average efficiency for the heads developed during this period was approximately 84 per cent.

In the case of the intermediate system, the average efficiency from operating records was 81.42 per cent, and from acceptance tests at heads developed during this period approximately 82 per cent.

The average high-lift plant capacity factor was 19.5 per cent with a load factor of 64.5 per cent.

Power Plant

Station electric loads include power for main pumping units in high- and low-lift plants, filtration plant, all station auxiliaries, and lighting. The maximum hour demand to the present is 10,350 kw. The average demand for the fiscal year ending June 30, 1936, was 4100 kw. During this period the turbo-generator-plant load factor was 69 per cent, capacity factor 24 per cent, and power purchased from stand-by service was 3.21 per cent of the gross output. Except for very short periods, loads were carried with one main 5000-kw unit and one 500-kw auxiliary unit in service. During maximum-hour pumpage in summer and high load on the heating system in winter two 500-kw units have been operated. Similarly in the boiler plant, only one of the two boiler units has been operated except infrequently under special load conditions. The maximum hour load carried to the present by one boiler unit was 97,000 lb of steam per hr which represents a rating of 323 per cent. The average boiler load for the fiscal year ending June 30, 1936, was 51,000 lb per hr or 169 per cent of rating.

Boilers

The boiler units have been operated through varying periods up to a maximum run of three months. With only two units installed and with somewhat limited maintenance forces there is an unavoidable maintenance period required of sometimes one month which makes reserve boiler outage quite high.

Fuels from western Pennsylvania and Harlan County, Ky., have been burned since the beginning of plant operation. A small portion of coal was run-of-mine but the major portion was 2-in. or $1^1/_8$-in. nut and slack. Both of these fuels are low in sulphur and have heat values within limits of 13,800 and 14,600 Btu per lb dry basis. Both may be designated as semicaking, but the Kentucky coal possesses some free-burning characteristics and has ash content of less than five per cent and ash-fusion temperature only slightly above 2500 F. The Pittsburgh district coal has ash content of about 8 per cent and ash fusion never less than 2575 F. With continuous and careful observation by operators both of these coals have been burned successfully in these stokers. The Kentucky coal, although used only since November, 1936, appears to be better suited for the link-grate section of the stoker because of its slightly free-burning characteristics, but the low ash content, the low fusion temperature, and the slagging in the underfeed section is already decreasing boiler runs and increasing stoker-part replacements. The cost of stoker replacement parts from initial operation to the end of 1936, was 1.7 cents per ton of coal burned.

The plant design calls for 350 lb gage 700 F steam at turbine throttle, but in operation the average steam temperature has been 670 F. The air heaters have such small apertures for the passage of gas that, even with superheated-steam soot blowing, some trouble has been experienced in prevention of filling the apertures with slightly caked soot or fly ash. To the present time no air or gas by-passes have been provided, and until such provision is made there remains the possibility of a forced shutdown of units because of this difficulty.

The boiler feed make-up water, which amounts to approximately 1.5 per cent is evaporated before entering the condensate system, and all feedwater is deaerated in the main condensers. The only other treatment used up to now has been sodium sulphite which is introduced into the boiler feedwater at the outlet of the closed heaters for reduction of the last trace of dissolved oxygen.

The internal surfaces of the boilers and the economizers are coated with "Apexior." The boilers have been in service for two years and careful inspection shows no trace of boiler scale and only very minor pitting has been detected at or near the water line of the drums and tubes. The treatment used usually results in a sulphate-carbonate ratio conforming with A.S.M.E. recommendations.

The temperature of stack gases averages only slightly over

TABLE 6 AVERAGE OPERATING TEMPERATURES AT BOILER LOAD OF 60,000 LB OF STEAM PER HR (SUMMER CONDITIONS)

FIG. 12 LIST OF ALL EXISTING MAJOR EQUIPMENT FOR PUMPING AND POWER PLANTS, AND ULTIMATE PLANT EQUIPMENT

200 F, which together with the fairly high values of carbon dioxide in flue gas, results in satisfactory overall boiler-unit efficiencies. Results of carefully conducted acceptance tests throughout the range of loads from 30,000 to 90,000 lb per hr, showed a maximum overall efficiency at 56,000 lb per hr of 87.1 per cent for the complete boiler unit. The average of monthly efficiencies, computed from the operators' logs taken from commercial meters, checks within two per cent with the results of tests made using special and carefully calibrated instruments.

Additional information in regard to temperatures is given in Table 6.

Turbogenerators

The main 5000-kw turbogenerators operate continuously with two-stage bleeding for feedwater heating and evaporation of feedwater make-up. The auxiliary 500-kw turbogenerators are operated continuously with one-stage extraction for station heating. Extraction in summer months is low, the maintaining of hot water for wash and shower rooms being the principal demand. Although all turbines normally operate extracting, acceptance tests in accord with contract terms were conducted with the units operating full-condensing. Because of this, it is impossible to make direct comparison of actual operating results and acceptance-test results. All units were opened and the rotors and stationary blading thoroughly cleaned with light fly-ash blast and were carefully checked for clearances and reconditioned before testing. The turbines when opened had been operated for periods varying from 4000 to 5000 hours and the rotors and stationary blading were partially covered with thin adherent deposits of iron oxide. The deposits were heavier and more adherent in the low-pressure stages.

Acceptance tests, as for all other equipment, were conducted by Department of Water Supply engineers and witnessed by manufacturers' representatives. The turbogenerator units were tested under conditions very nearly as prescribed in the contracts with the one exception that the temperature of the steam instead of being 700 F was 660 to 670 F. Test results with all corrections made to contract conditions gave steam rates at 5000 kw load and 0.8 power factor on main units of 10.03 and 9.96 lb per kwhr and rates at 500 kw for auxiliary units of 13.56 and 13.85 lb per kwhr.

Overall Station Economy

The following economy figures are for the pumping and power plants for the calendar year 1936:

The thermal efficiency of the pumping plant was 16.06 per cent. The fuel rate was 1.136 lb of dry coal per net generated kwhr. The average equivalent evaporation was 12.35 lb of steam per lb of dry coal from and at 212 F. The average plant water rate was 11.91 lb of steam per net kwhr. The electric power per whphr was 0.927 kwhr. The coal required to pump one million gallons 100 ft high for the Springwells Station was 479 lb.

Conclusions

Now that the department operates two stations involving generation of steam or power to operate pumps and purification plants, it would normally be expected that some comparison of operating results secured should be presented. It was, however, considered inadvisable to attempt such a comparison because of lack of detailed operating data for the Water Works Park Station. Just for a general comparison, it may be stated that the average cost of pumping water, exclusive of fixed charges, for the period from April 1, 1935, to December 31, 1936, was \$6.62 per million gallons for Springwells and \$8.13 for Water Works Park. During this period the division of load was approximately, Springwells 45 per cent and Water Works Park 55 per cent of total pumpage. The average costs of purification for the same period have been, Springwells \$2.52 per million gallons and Water Works Park, \$2.98.

Since the Springwells Station has been in operation and even during the first summer while, due to the depression, city demand for water was still low, it was evident that the new station was not only a distinct advantage for normal loads but a real necessity for maintaining distribution-system pressures in all locations in the system during maximum-load conditions.

Much credit is due the general manager, George H. Fenkell, water commissioners, consultants, and other city officials during the period of planning and construction for their continued and untiring efforts which finally produced an essential station as an auxiliary to the lone and old original Water Works Park Station.

Application of Tension-Impact Tests

By G. F. JENKS,[1] WATERTOWN, MASS.

Impact testing as normally performed with notch bars is objectionable because of large errors inherent in the method of test, and especially those due to errors in machining the notch. Notch tensile specimens are more satisfactory being less sensitive to errors of machining or to accidental variations in structure of the material.

In studying tension-impact specimens it was found that materials required a constant energy to rupture independent of the velocity of loading provided certain critical velocities were not exceeded. This critical or "transition" velocity appears to be a fundamental property of a material. Its value varies with chemical compositions and with both preliminary and final heat-treatment, and it also varies with the temperature of test.

The study of "transition" velocity is a sensitive tool in research work, both in the development of processing methods and in physical metallurgy. The tension-impact test is a simple test to determine completeness of processing, and affords the design engineer information both as to the safety of the material and its ability to withstand impact loading.

ALTHOUGH impact testing had aroused sufficient interest to result in a symposium by a national engineering group in 1922,[2] it is little used today. The term receives no mention in the 1936 index of A.S.T.M. Standards of Metals. It is true that this method of testing is designated in some A.S.T.M. specifications, as for example, A63-36, which requires the use of 1640 and 2240 lb tups falling from heights up to $17^1/_3$ ft. The A.S.T.M. Tentative Standards, 1936, does prescribe "Tentative Methods of Impact Testing of Metallic Materials," E 23-34T and includes as an appendix an apology for the method.

Impact tests are prescribed in other specifications and producers of materials publish many data on impact properties at normal and at low temperatures in advertisements of special processing methods or special compositions. Such tests are also widely employed in research work on the properties of materials at low temperatures and to some extent in studying failures.

The significance of the test, however, has been vaguely understood. The design engineer notes it in the selection of materials but makes no direct application of it in the calculation of stress distribution. He considers the ductility as measured by the static tension test to be a measure of the safety of his structure and carefully prescribes elongation and reduction of area in addition to yield and tensile strengths. Impact strength he leaves to the metallurgical engineer as one of those elements included in the factor of safety or, as some express it, the "factor of ignorance."

Two of the main reasons for these conditions are the form of the test specimen and the nature of the test. The sensitive portion of the specimen is the notch. Various forms such as keyhole and V notches are in use. Much has been written concerning the virtues and vices of various notches and methods of machining them. Under stress concentration these notches are extremely sensitive to errors of machining or to differences and irregularities in their surface. In the notched-bar specimen the rupture originates in the notched surface. Stress concentration around tears and irregularities of surface will determine the origin of fracture and the time at which rupture starts. If fracture originates prematurely the energy required will be abnormally low.

The volume of the notch, especially the V type, may be modified considerably by errors in machining the radius of the fillet at the bottom of the notch, and also by tearing the surface of the fillet. The energy required to break the bar varies with the volume of the notch.

Impact tests, as usually employed, are high-velocity bend tests. Stresses across the section under plastic flow are variable in intensity and are difficult to analyze. Most of the energy required is absorbed in plastic working of the metal. With a variable width of notch it is impracticable to predetermine the volume of metal which will receive plastic working. It varies with the yield strength and the yield ratio of the specimen. If a fracture originates around an irregularity of machining or of structure, the results are a measure of surface condition rather than of the ability of the metal to absorb energy under conditions of high velocity loading.

It is not to be inferred that notched-bar impact tests are without significance and that they do not disclose useful properties of materials. Rather, it is concluded that the test is difficult to evaluate and that the errors of tests are inherently large.

At Watertown Arsenal the transverse notched-bar impact tests were abandoned about ten years ago for the reasons just briefly discussed, and a notched tension-impact specimen was substituted. The ordinary Charpy pendulum impact machine is used in the test. The notch is a truncated V with a flat 0.05 in. wide. No particular care is taken in machining the fillet between the bottom and the wall of the notch as the volume of the notch does not vary appreciably with errors in its dimensions. Recent investigations discredit the truncated V notch in favor of a square notch. The specimen has been fairly satisfactory, however, in the development of methods of processing steel, in studying failures of material, and in inspecting purchased materials.

In its research work and in the development of welding technique, the Arsenal has also employed long-notch tensile specimens. Normally the length of a long notch is the gage length of the static tension test specimens. In comparing the energy absorbed in static and dynamic tests, abnormalities in the behavior of certain materials were observed. This led to investigations, the results of which have been published.[3] From this work two fundamental properties of metals were disclosed:

(1) Provided certain critical velocities are not exceeded in tension-impact testing, the energy required to rupture a specimen

Contributed by the Iron and Steel Division for presentation at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

[3] "The Relation Between the Tension Static and Dynamic Tests," by H. C. Mann. Proceedings of the American Society for Testing Materials, vol. 35, part 2, 1935, p. 323. Also: "High Velocity Tension Impact Tests," by H. C. Mann, Ibid., vol. 36, part 2, 1936, p. 85.

of given section and length is independent of the velocity of application of load. The energy required to rupture a specimen in tension impact may be calculated from the curve obtained from the results of the static tension test in which the ordinate is the load multiplied by the ratio of the original to the reduced sectional area, and the abscissa is the total elongation.

(2) Beyond certain critical velocities this relationship no longer holds. This "transition velocity" varies with chemical composition and structure and appears to be a fundamental property of metals.

A third fundamental property of tension-impact specimens will be discussed by H. C. Mann in a paper to be presented at the annual meeting of the American Society for Testing Materials.

TABLE 1 EFFECT OF LENGTH OF NOTCH UPON IMPACT PROPERTIES

Notch length, in.	Velocity, fps	Energy: Total, ft-lb	Energy: Per unit volume, ft-lb	Elongation, per cent	Reduction of area, per cent
0.025	10	28.0	22,400

	10	140.0	2,800	33.0	57.8
	20	145.5	2,910	35.0	57.8
	28.5	140.0	2,800	33.0	57.8

In these concepts of impact testing, the velocity factor is emphasized. This is as it should be. This "transition velocity" is a fundamental property of metals as much as yield strength, tensile strength, and ductility. The impact strength in foot-pounds is a derived value which can be calculated from other primary values. Only when the transition velocity is exceeded does the impact strength become of interest to the metallurgist or the design engineer. Unfortunately, impact-testing machines available in the past have been operated at fixed speeds of 11–17 fps and the form of test specimens has emphasized stress concentration rather than rate of application of load.

Within certain limits the energy absorbed by a given specimen is independent of velocity; it follows that the impact value is independent of the type of machine employed. This is shown by experimental data in which energy values calculated from tests made on static machines are duplicated in machines of both the pendulum type and of the rotary type. The relationship holds for short and long notches.

As a corollary of constant energy, it should follow that the ductility of material is independent of the velocity of test. This accords with experimental data.

Table 1 illustrates these conclusions. The material used was a 1-in. rolled bar of 1035 steel (K-20) received in the annealed condition,[4] and renormalized at 1650 F after holding 3 hr. The data were obtained on a pendulum-type machine, except that the values for zero velocity are computed from the results of the static-tension testing machine. The diameter of notch of the specimen was 0.252 in. The transition velocity of this material in the normalized condition is in excess of 28.5 fps.

The properties of metals for velocities of application of loading greater than the transition velocity is not within the scope of this study. It is sufficient to state that the work required to rupture falls off rapidly for velocities beyond the critical one.

Experimental data indicate that for notches from 0.2 in. long to the gage length of standard tensile specimens, the transition velocity is independent of the notch length.

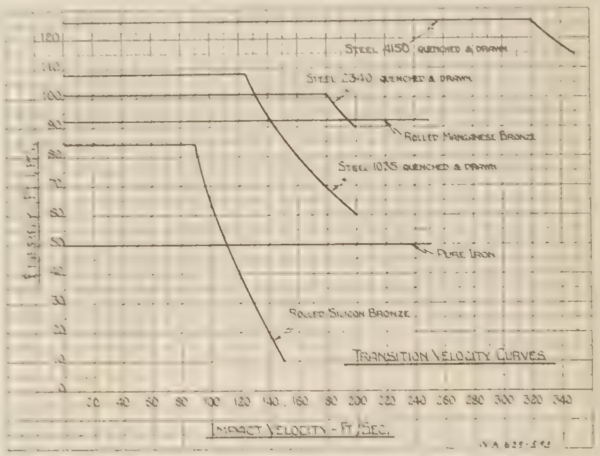

FIG. 1

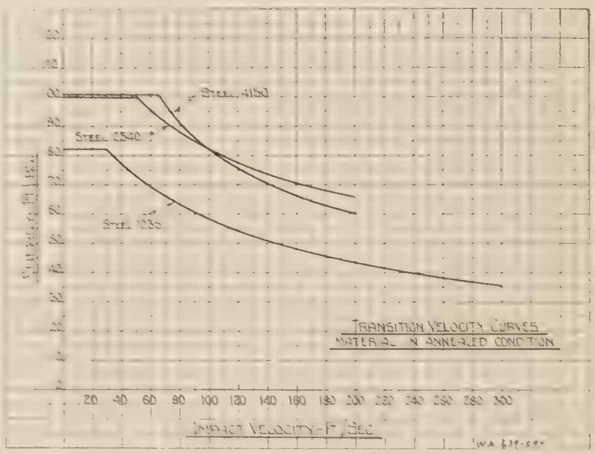

FIG. 2

The transition velocity varies with composition of the metal as shown in Fig. 1.

The transition velocity varies with heat-treatment. Fig. 2 shows values for some materials in the annealed condition, whereas in Fig. 1 the values are given for the quenched and drawn condition. A comparison of Figs. 1 and 2 indicates the change in this transition velocity with structure. The tests were made on material from the same bar of the compositions given. Heat-treatment was the only variable.

Table 2 shows the change in transition velocity for a bar of 1035 steel (K-20) air-cooled from 1700 F (held 3 hr), water-quenched from 1550 F (held 1 hr), and furnace-cooled from the temperature specified after holding 3 hr.

[4] For a history of this material see "Report on Low Temperature Impact Tests," Proceedings American Society for Testing Materials, vol. 36, part 1, 1936, p. 132. Heat-treatment of the material as received is referred to on first page of report.

Fig. 3 shows variations in transition velocity as a function of draw temperature.

Some materials are subject to temper brittleness. In the brittle condition these materials apparently possess transition velocities below those ordinarily used in impact testing, and impaired impact properties are disclosed by ordinary tests. A study of critical velocities of loading presents a different angle to the problem of brittleness, as indicated in Table 3. The data were obtained from a bar of chrome-nickel steel (WD 3435) oil-quenched from 1450 F (held 2 hr). One group of specimens was then oil-quenched from 1160 F (held 2 hr) and the other group furnace-cooled after holding 2 hr at the same draw temperature. The diameter of specimen at the notch was 0.357 in. For zero velocity the energy was calculated from the static tests.

TABLE 2 EFFECT OF TEMPERING UPON IMPACT PROPERTIES

	25	345.0	...
	28.5	289.0	320.0

For the material quenched from the draw, the transition velocity is near the velocity of standard impact machines, whereas for the furnace-cooled bars the transition velocity was well below that velocity. The difference in transition velocities is not great but of such nature that the ordinary impact test brought it out. If the transition velocity rather than the impact strength be considered, the use of this material however heat-treated must be questioned for some applications. In such cases of low transition velocities, the impact strength as measured in foot-pounds is no indication of the safety of a structure subject to impact loading.

The impact strength of cast steels is sensitive to diffusion heat-treatments as illustrated in the case history of a casting of the following chemical composition: Carbon 0.38, manganese 0.53, silicon 0.20, sulphur 0.022, phosphorus 0.018, molybdenum 0.30, vanadium 0.09 per cent. The original heat-treatment was: held 8 hr at 960 C, air-cooled; held 6 hr at 850 C, furnace-cooled; held 4 hr at 860 C, water-quenched; held 6 hr at 700 C, furnace-cooled. After this treatment the impact strength, measured upon a truncated V notch in tensile impact, was 7.5 ft-lb. After a complete reheat-treatment identical with the first, the impact strength was not sensibly changed (8.8 ft-lb). After a diffusion treatment in which the material was held 25 hr at 1150 C (air-cooled) and then retreated through approximately the same cycle as before, the impact strength was raised to 30.5 ft-lb. In this case the ductility varied in much the same proportion. The transition velocity was not determined, but from a comparative study of this and other castings of similar composition and treatment, it is apparent that the transition velocity of the material as originally treated was well below 15 fps, whereas after high-temperature treatment the critical velocity is well above that figure. It is believed that further investigation will show that the transition velocity is extremely sensitive to the diffusion treatment of steel.

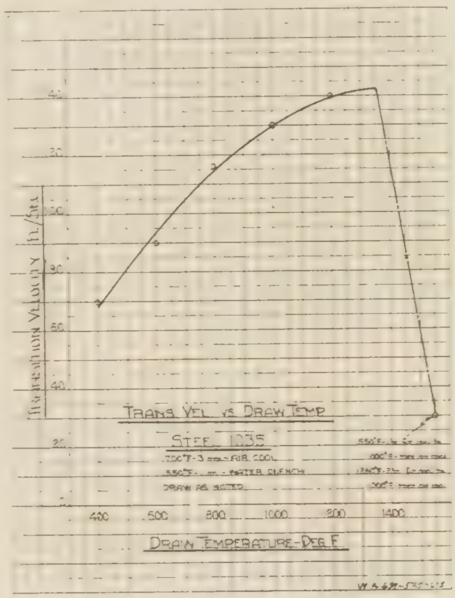

Fig. 3

Warner[5] reports that for one composition of steel plates for welding a stress-relieving treatment (600 C) raised the transition velocity from 30 to over 150 fps without appreciable change in energy recorded by the test. For another composition, the stress-relieving treatment increased the energy to rupture by about 15 per cent, whereas the transition velocity was increased from 37 to 100 fps.

It has long been known that the impact strength of materials was affected by low temperatures. In the reference in footnote 4 of this paper results are disclosed on a 1035-steel (K-20) including tension-impact results (see Fig. 6 of that reference). As these results did not include a satisfactory correlation between tension-impact and V-notch and keyhole-notch transverse tests, a more complete investigation of the material was made. The material used was the same lot of K-20 steel, except that it was heated to 1650 F, held 3 hr, and air-cooled. The departure from the original treatment was accidental. All results at low temperatures were determined while the specimen was held in a bath at prescribed temperature.

[5] "Arc Welding of Structural Alloy Steels," by W. L. Warner, Trans. A.S.M.E., vol. 58, no. 7, 1936, p. 515.

The properties of this material as measured by static tension tests are plotted in Fig. 4 for a 0.252-in. specimen (1 in. gage length).

In Fig. 5 are shown in full line the load-elongation curves for

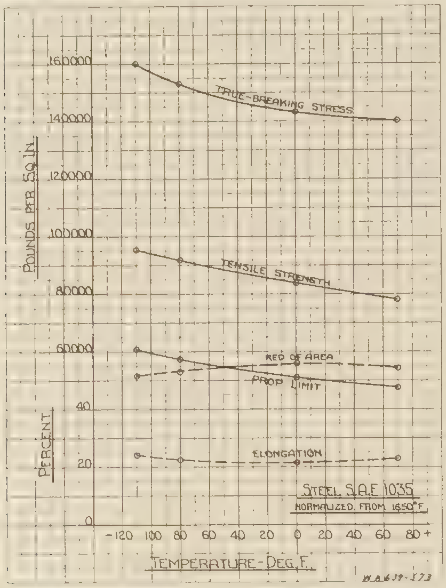

FIG. 4

specimens with two lengths of notches and at the extreme temperatures used. In the upper curves for each temperature the ordinate is the load multiplied by the ratio of the original section

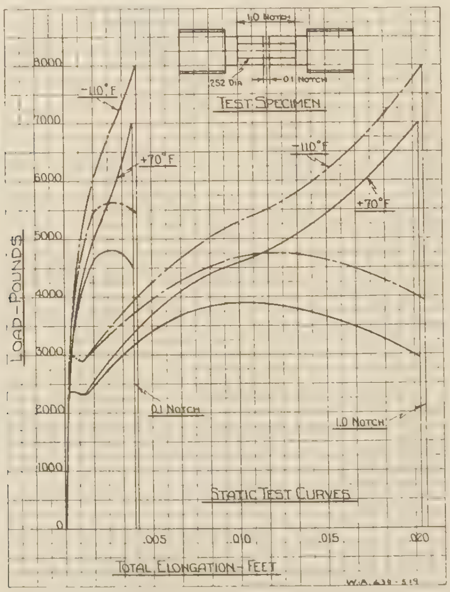

FIG. 5

to the reduced section. The energy for zero velocity is calculated from this curve. The true breaking stress of Fig. 4 is proportional to the maximum ordinate of this curve.

The results of impact tests are tabulated in Table 4. The results of tests are shown graphically in Fig. 6.

If the energy absorbed is reduced to energy per unit volume of

the notch, the results (see Fig. 7) are of great interest; they illustrate the effect of stress concentration upon the transition velocity. This is shown directly in Fig. 8. In Fig. 9 the results of the tension-impact tests are compared with those referred to in footnote 4 of this paper. It is to be noted that the very short

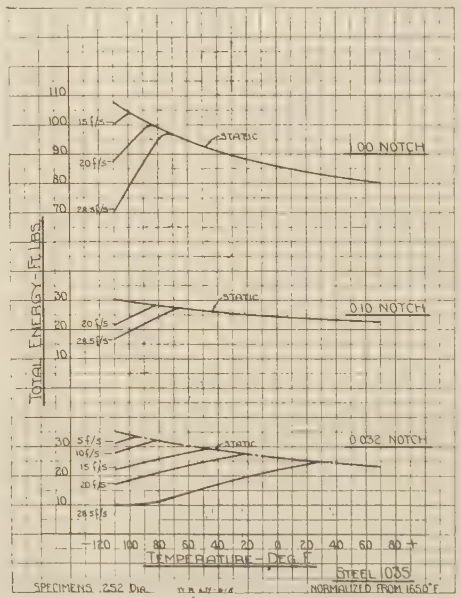

FIG. 6

notched-tension specimen possesses a sensitivity similar to that of the V notch. Experimental work is being conducted on an even shorter notch. The advantage of the tension specimen lies

in furnishing information by which an optimum impact-energy curve can be constructed and by which the effect of velocity of loading can be analyzed. Such information should furnish a clue to the physical metallurgist in the study of the structure of metals as affected by temperature. The concept of critical velocities of loading should clarify some of the impact phenomena which have been a source of difficulty to design engineers and metallurgists. It offers an extremely sensitive method of test to judge the effect of changes in processing and composition of metals used under extreme conditions.

In tension-impact testing the energy values are sensitive to nonhomogeneities of the test specimen and especially to those located near the surface. By examination of the fracture it can be determined whether abnormal values are due to unusual defects such as errors in machining, internal cracks, slag, nonmetallic particles or other defects of a local nature, or to improper or insufficient heat-treatment. Abnormal values of a discontinuous nature not representative of the material may be recognized and discarded. Results of tests are not highly sensitive to errors or irregularities in machining. By careful examination of the

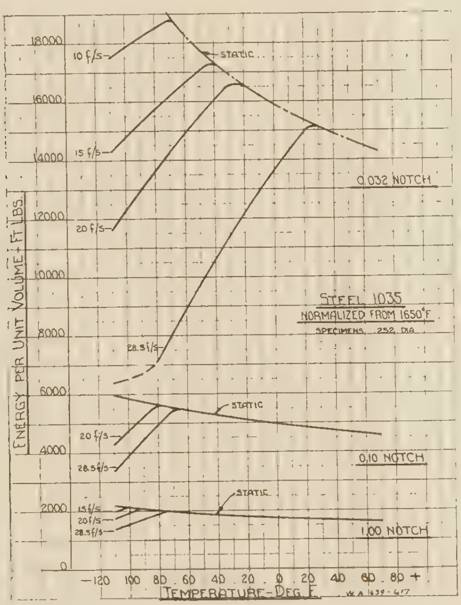

FIG. 7

fracture, rather reliable opinions as to irregularities and incompleteness of processing can be formed. The fracture of the transverse (notched-bar) specimen is more difficult to interpret and yields less information as to the quality of the metal. The quality of the machined surface of the notch is overemphasized. The errors of testing are of smaller magnitude in the tension specimen. In the tables included in this paper, all tests made in the series are recorded. Of course abnormally low results are obtained. The cause is generally apparent in the study of the fractured surface.

Conclusions

Impact strength of materials, within certain limits of velocity application of loading, is a derived value.

The transition velocity is a fundamental property of metals. The ability of metals to absorb energy is limited beyond a critical velocity of application of stress.

Tension-impact tests permit the separation of this fundamental property from the record of impact strengths and the determination of the optimum values.

In research, the tension-impact test is capable of extreme sensitivity to structural changes in metals.

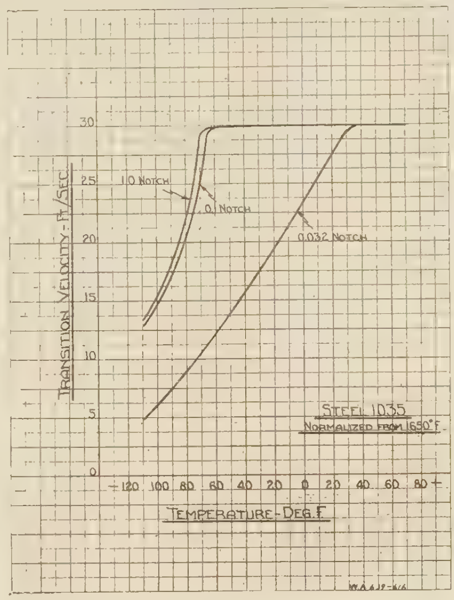

FIG. 8

New problems are presented to the physical metallurgist to explain why metals are sensitive to the velocity of loading. A new method is offered to study physical phenomena and technological processing.

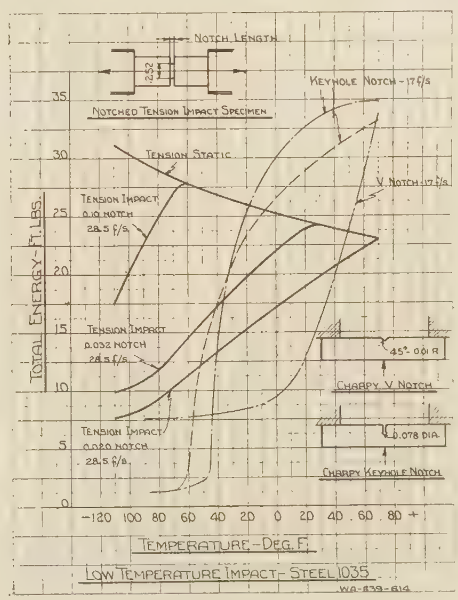

FIG. 9

The introduction of the concept of transition velocity into impact testing gives the design engineer another factor to consider in the selection of materials. Materials of given physical

properties as expressed in strength and ductility, are not interchangeable as to use. If the velocity of application of loading is a factor, the transition velocity of the material becomes one of the most important elements in the selection of chemical composition of the material and its heat-treatment.

If the tension-impact test is to be used as an inspection tool to determine the completeness of processing, the velocity of test should be just under the transition velocity inherent in well-processed metal of the composition and structure specified.

The experimental work recorded in this paper was carried out by H. C. Mann, senior materials engineer at the Watertown Arsenal. His studies and reports are the basis of this study.

Maintenance of High-Speed Diesel Engines on the Canadian National Railways

By I. I. SYLVESTER,[1] MONTREAL, CANADA

This paper sketches the application of Diesel-electric equipment to rail traction on the Canadian National Railways, and deals particularly with experiences in the maintenance of high-speed Diesel engines since 1925. The circumstances surrounding the early application of this type of motive power are briefly explained. Problems of repair by steam-locomotive maintenance organizations are outlined. The important records pertaining to performance and measurements of wear occurring on various parts of Diesel engines are described. Typical examples of records developed in handling pistons, cylinders, and crankshafts, which were employed in arriving at a systematic handling of these parts, are illustrated. This is followed by an explanation of curves covering the average rate of wear found on different groups of engines taken from records extending over many years. Brief reference is made to maintenance methods developed in steam-locomotive service and advantageously extended to Diesel repairs. These include illustrations on electric and acetylene welding, together with some experiences with hard chromium plating, employed to extend the life of active engine parts. The paper is concluded with an explanation of the trends of various factors which make up the cost per car-mile of Diesel-engine operation, and relate particularly to engines which have seen considerable service.

The purpose of this paper is to present the results of experience gained in the maintenance of high-speed Diesel engines on the Canadian National Railways. Some 12 years ago the necessity of handling economically traffic of small proportions was recognized, and therefore careful studies were made of existing types of motive power from which it was decided that the self-propelled car using an internal-combustion engine was most suitable for the intended service. The lightweight high-speed Diesel engine, because of its compact size and relatively high thermal efficiency, was chosen for the power plant.

In the beginning, the object was not to provide a de luxe service beyond that offered by steam trains, but rather to substitute Diesel-electric rail cars on runs then operated at little or no profit, and on lines having relatively light traffic. In the light of recent developments on other railroads of high-speed Diesel-powered trains with streamlining, air conditioning, and luxurious appointments, the original venture of the Canadian National appears rather modest.

The choice of lightweight high-speed Diesel engines for rail service was extremely limited in those days, although it has expanded tremendously during the intervening years. Today we are operating rail cars and locomotives ranging from 200 to 1330 bhp. However, this particular paper will deal only with the maintenance of three principal groups of rail-car engines of from 200 to 350 hp, comprising 26 units which have run over ten million miles in passenger service. These engines were placed in service in 1925, 1927, and 1930, and even though they include improvements evolved over a five-year period, their maintenance problems are almost identical.

Soon after the commencement of Diesel-electric rail-car service, it was recognized that the oil-electric car offered great possibilities for economical operation and high availability, provided a satisfactory program for maintenance could be worked out. The lack of experience and knowledge on the part of those called upon to handle the engines, and of the designer and builder, regarding operating conditions, was a serious handicap in the early days. The seniority system, commonly followed in railway organizations, sometimes mitigated against the selection of the most capable men. Also the locomotive-shop staff had not previously been called upon to perform the type of work required in maintaining the fine working clearances of the wearing parts. However, these conditions have been quite general on railroads on this continent and are mentioned here only because they had such an influence on the amount and type of maintenance required.

The most desirable condition is found in large numbers of identical equipment, centrally located, as expert supervision can be provided and the staff soon becomes accustomed to the new routine. The other extreme is found in rail-car service where the units are operated over an extremely wide territory, which interferes with efficient training and seriously affects availability of the equipment due to deadheading to and from a centrally located repair point. This latter condition applies particularly on the Canadian National Railways, and the maintenance methods which follow were developed to cope with this situation. All these problems have demanded as much attention as the technical difficulties—possibly more.

A general arrangement showing sections through the types of engines to which this paper applies in particular is shown in Fig. 1. They are four-cycle, direct-injection engines of both British and American manufacture, the original research work having been carried out by the Wm. Beardmore Company at Glasgow prior to 1924 and the later development by the Westinghouse Company at their South Philadelphia plant. The crankcases of these engines are of cellular type, arranged for separate cylinder liners and made of cast steel. The crankshafts are supported in main bearings between each cylinder. Collar studs hold the individual cylinder heads and liners to the crankcase, the main bearings being attached to the crankcase in a similar manner. The crankshafts are of carbon, nickel,

[1] Special Engineer, Operation Department, Motive Power and Car Equipment Sections, Canadian National Railways. Mr. Sylvester was educated at Vancouver, B. C. He served a five-year apprentice course, which included technical training, with the Canadian National Railways and then spent two years in the mechanical-engineering department, testing locomotives and appliances with the dynamometer car. His first experience with railway Diesel equipment was in 1925 when the original Beardmore engines were installed and a record-breaking run was made from Montreal to Vancouver. Since then his work has been directly associated with Diesel-equipment construction and maintenance. He was transferred to Montreal in his present capacity in 1931.

Contributed by the Railroad Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

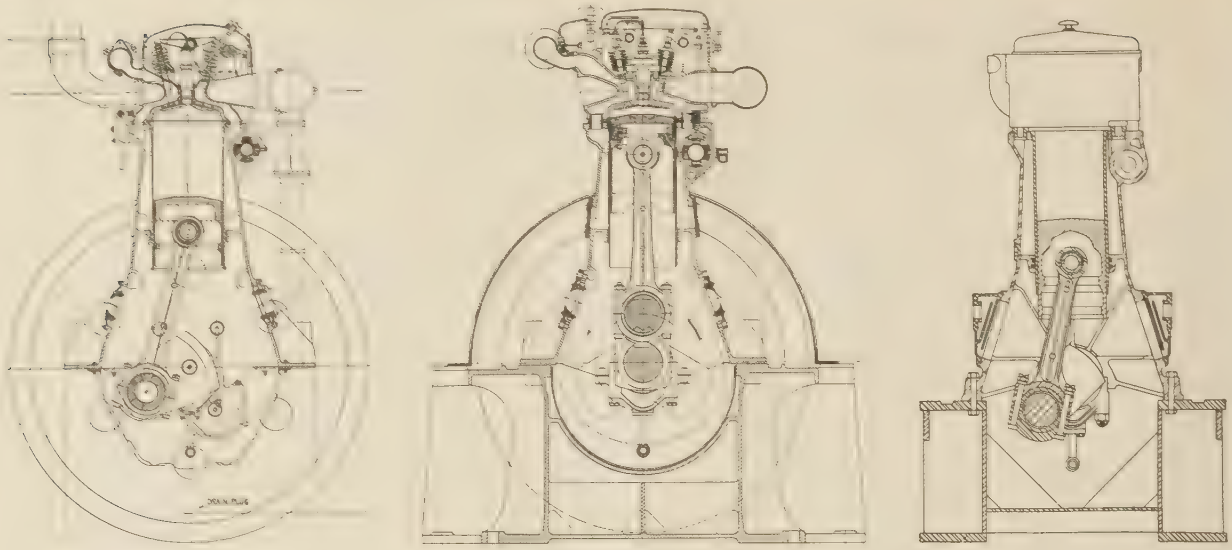

Fig. 1 Sections Through High-Speed Diesel Engines of From 200 to 350 Hp Used on the Canadian National Railways

and chrome-nickel steel forgings machined all over and drilled for pressure lubrication from the main journals to the crankpins. Cast-aluminum cylinder heads with steel valve seats to accommodate dual inlet and exhaust valves are also used on all these engines. Each head carries its rocker-arm mechanism and a single atomizer which is located at the center of the head where it is easily removed. Aluminum pistons, hollow floating wrist pins, and forged-steel connecting rods are also features of these engines. The development of crank end bearings for the connecting rods has been of considerable interest and will be dealt with later.

The cast-steel crankcase and underbed of thin section, together with rather extensive use of aluminum for such parts as pistons, cylinder heads, and gear cases have resulted in weights between 16 and 24.2 lb per bhp for these engines, which is in the lightweight class for rail service. The essential particulars of these units, which were the subject upon which maintenance investigations were carried out between 1925 and the present time, are given in Table 1. These include two columns of figures

Number of scraper rings	1	3

showing the maximum and minimum sizes, weights, and conditions. The tabulation of the extremes in Table 1 indicates the design limits of the principal rotating and reciprocating parts around which most of the maintenance problems have centered.

The first feature of our maintenance consists of daily reports made out to show the fuel, lubricating oil, and other supplies used, mileage operated and load hauled, together with any trouble experienced during operation, and finally the repairs and inspection which are made daily. These data are compiled monthly to show the average condition obtaining for each car and, as all the equipment is included in this report, it permits the individual maintainer to compare his performance with that of others. This report also shows any troubles which occur with such frequency as to warrant investigation, thus keeping problems in order of their importance before the supervising staff. An analysis of these records over extended periods of operation also indicates any inherent weakness which can be remedied in new designs.

In a general way the practices developed are a combination of railway maintenance ideas and those used in the repair of gasoline engines. Many of the methods employed are quite in line with those generally accepted in fleet operation of trucks and busses. In fact, much inspiration has been drawn from this source when grappling with the more difficult problems. In these installations engine size and weight have been kept to a minimum with the result that provision for successive wear and remachining is not generally made to the same extent as in steam-locomotive work. One principal difference lies in the rather extensive use of welding and, of late, chromium plating as a means for reconditioning wearing parts. Fusion welding, as developed in steam-locomotive service, is now being used extensively in Diesel-engine repairs and much progress has been made in recent years in the use of the electric arc and acetylene flame for the building up of worn parts as well as repairing fractures. Good results were not obtained in this new application without overcoming several technical difficulties because the original development on the railway had to do with structural-steel plates and boiler work in which the metal was quite readily welded. However, in the repair end, large varieties of special metals had to be dealt with and in many instances heat-treatment to regain physical properties of the finished part became a problem.

Considerable ingenuity has been required to develop successful welds on such parts as pistons, cylinder liners, and valve gear. The service engineers of companies which supply welding materials have been of great assistance in the development of suitable welding rods for this work and in providing instructions for their satisfactory use. This process is now responsible for reduction in our maintenance costs and some descriptions of unusual repairs by this method are given under various headings which follow.

Within the last year or so we have been investigating the merits of hard chromium plating in an effort to lower the rate of wear on certain parts and also as a means of regaining the original size where possible. Worn surfaces on pins and journals of crankshafts, wrist pins, cylinders, and various other small parts have been built up with chromium and satisfactorily salvaged. This type of plating must not be confused with the decorative plating which is used more or less in the form of a lacquer to preserve the copper-nickel plating underneath, as it is applied directly to the base metal. We are using thicknesses varying from 0.003 to 0.015 in., depending on service conditions. Excessively thick plates are not found desirable and, for that reason, the original sizes are not always regained. Ordinarily, although sufficiently tough and adherent for bearing conditions, this plate will not endure excessively high unit pressures or shock. For example, in a Brinell test, the high-pressure load of the ball in making the impression will crack the plate and the reading will be practically in line with the base metal underneath. We have taken readings on plated parts with the Firth diamond tester which makes a small impression in the plate and is not affected by the hardness of the base metal. When these readings are converted into the Brinell scale they range from 650 to 900, which is considerably harder than any bearing surface usually encountered.

Our work so far has been limited to steel parts and some fine examples of hard, smooth surfaces with the plate varying only around one-half thousandth have resulted. The shape and placing of the anodes have a very marked influence on the regularity of the plate, and, when these conditions are well understood, it is possible to return the part to service without machine work. It is desirable, however, to grind and polish the finished piece to insure regularity of the bearing surface. When this finishing is carefully carried out, a hard, low-friction, wear-resisting surface is produced and the service to date indicates that long life can be expected from these parts. The mechanics who are handling these plated parts are very much impressed with a journal which can be rubbed with a file without destroying its finish. In the plating, the condition of the surface of the base metal is reproduced in the finest detail and it is, therefore, necessary that the part be very carefully and accurately ground

Fig. 2 Record of the Rate of Piston and Cylinder-Liner Wear

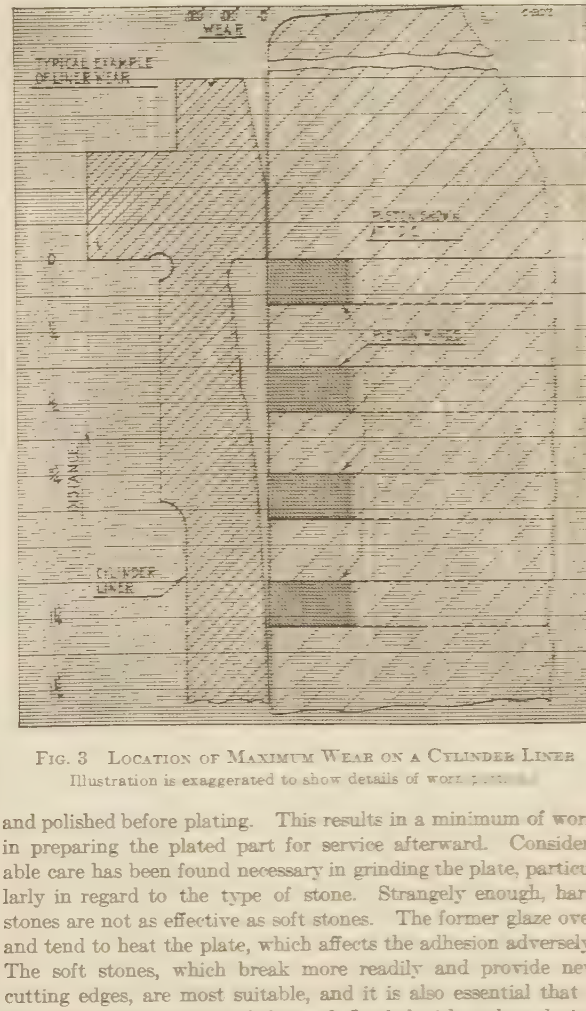

Fig. 3 Location of Maximum Wear on a Cylinder Liner
Illustration is exaggerated to show details of worn

and polished before plating. This results in a minimum of work in preparing the plated part for service afterward. Considerable care has been found necessary in grinding the plate, particularly in regard to the type of stone. Strangely enough, hard stones are not as effective as soft stones. The former glaze over and tend to heat the plate, which affects the adhesion adversely. The soft stones, which break more readily and provide new cutting edges, are most suitable, and it is also essential that a very light cut be taken and the work flooded with coolant during the process. The time necessary to remove the excessive plate is such as to warrant great care in preparing the parts and in bringing them up to a diameter only slightly in excess of the required size. This, of course, requires a complete knowledge of the rate at which the plate is being deposited, so the thickness can be judged on a time basis.

Cylinders

The cylinders in these engines are in the form of relatively thin tubing, accurately machined all over, and are snugly fitted in the crankcase. They are of the wet type, being surrounded by cooling water, and the joint at the bottom is made by means of rubber rings. This construction, which is now generally accepted for this type of engine, is well suited to maintenance because of the ease with which the cylinder can be removed for repairs or replacement.

Our lack of information regarding the rate of wear on cylinders

and pistons of rail-car engines, some ten years ago, resulted in the introduction of a system of recording the sizes whenever these parts were dismantled. A copy of the form which has been used for recording this information is shown in Fig. 2. At first it was felt that these records would give us an indication of the direction of wear around the circumference of the cylinder and possibly lead to correction of it. However, there was found to be no regularity in this regard, some 60 per cent showing maximum wear at right angles to the crankshaft and the remainder lengthwise or at some intermediate angle. We have been unable, even by painstaking study of a great number of measurements, to associate this feature with any other detail of engine construction or performance. The principal value of this form has been in the determination of average rate of wear on cylinders of different groups of engines, thereby providing a basis for the maintenance program. The comparison of wear

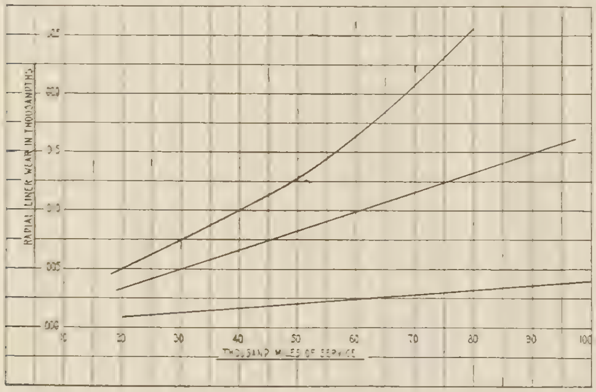

Fig. 4 Average Rate of Cylinder Wear in Rail-Car Engines

resulting from the use of different fuels and of different cylinder materials has also been gained from these records, and they have also shown the accuracy with which replacement cylinders are installed.

A typical example of the location of maximum wear is shown in Fig. 3. This picture is exaggerated to show the details of the worn portion. Although the wear is always greatest at top dead center, it is rather unusual for it to be almost entirely confined to such a short distance from top-ring travel. The wear at midstroke is always negligible and is only perceptible at bottom dead center on these engines.

What can be accomplished in reconditioning cylinders for further operation is, in the main, controlled by the number of engines involved. Several factors, however, must be given careful consideration, and too much emphasis cannot be placed on the value of accurate measurements of the wear occurring on both the pistons and cylinders. The analysis of these data permits important decisions to be made, such as: Whether reconditioning will be necessary and economical on both of these parts or if this attention can be confined principally to the cylinders. Where piston wear is relatively low, it is most economical to regain the original cylinder size by applying a bushing to existing cylinders as in locomotive service, thus avoiding any necessity for work on the pistons or supplying off-size rings.

Fig. 4, which was drawn from an inspection of a large number of forms such as shown in Fig. 2, shows the average rate of wear on the three groups of engines which we have in passenger service. An analysis of cylinder wear on individual engines produces a curve showing a gradual increase in wear up to 45,000 to 55,000 miles and then the wear is accelerated considerably. The shape of the top curve is more in line with the usual individual

TABLE 2 SIZES AND LETTER DESIGNATIONS FOR PISTONS AND CYLINDERS

Symbol	Size	Symbol	Size

B	0.050 in. oversize	*F*	0.050 in. undersize
C	0.025 in. oversize	*G*	0.075 in. undersize
D	Standard size	..	....

engine investigations. However, in plotting several hundred measurements, it is impossible to establish anything but a straight line as being the average rate of wear which can be expected. These curves are all the result of wear at top dead center on mild-steel cylinders which are fitted with aluminum pistons.

There are over 150 cylinders of similar type and size in service, which has permitted the establishment of sizes both above and below those which were set up by the manufacturers. It has been found that $^1/_{16}$ in. wear on diameter can be economically tolerated, giving due consideration to the increase in lubricating-oil consumption which results from wear on this part. In reconditioning, however, steps of 0.025 in. are desirable and economical in the reclaiming methods described later. It requires about 0.075 in. oversize to clean up properly a cylinder worn $^1/_{16}$ in. because of the wear being quite eccentric, or otherwise irregular, relative to the center line of the cylinder. In establishing these sizes it has been necessary, of course, to consider them in relation to similar steps on the pistons and the stocking of seven sizes of piston rings to suit. In the beginning, existing cylinders were bored out and oversize pistons applied. Later, as a result of an accumulation of worn standard-size pistons, undersizes down to 0.075 in. below standard were established. The symbols for size identification, which are stamped on both pistons and cylinders, are shown in Table 2.

Fig. 5 Worn Portion of Cylinder Repaired by Electric-Arc Welding

Fig. 6 Cylinder-Liner Chromium Plating on the Worn Portion Which Extends About 4 In. Down From the Top-Ring Travel

The arrangement does not require the previous size of the piston to be removed, but merely the addition of the new size. On cylinders, the sizes are stamped on the outside diameter of the collar which extends above the crankcase where it can be observed without removal of the head on most of the engines. The curvature of this surface permits easy removal of the previous size symbol when the cylinder is being rebored.

We are also reconditioning cylinders by depositing a band of metal on the worn portion for about 3 in. down from top dead-center position, with the electric arc. The cylinder is cleaned by grinding with a hand grinder to remove the surface metal and it is revolved during the welding process to keep distortion to a minimum. No attempt is made to regain the cylinder size by this method, but they are bored out about 0.015 in. above the original size and ground to 0.025 in. oversize. This means that a cylinder might be worn $^1/_{16}$ in., but be returned to service only 0.025 in. larger than previously. A section through the upper part of a cylinder which has been reconditioned in this manner is shown in Fig. 5. This enlarged section shows the typical porosity of the electric weld. The deposited metal, however, is considerably harder and more wear-resistant than the original cylinder material. The pores possibly are an advantage in regard to the retention of lubricant on this zone where the high temperatures often interfere with proper lubrication.

Fig. 6 shows a cylinder liner from one of the six-cylinder engines which was chromium plated at the worn portion for about 4 in. down from the top-ring travel. This was taken while the cylinder was being reground after plating. It had been worn about 0.024 in. on diameter and was plated sufficiently to bring it back to standard size and about 0.010 in. to clean it up. The vertical marks from the original use of this cylinder and the ring formed at bottom dead center are noticeable. A witness mark of the groove caused by maximum wear at the top is just in evidence and was removed during the finish-grinding. It is possible to set up these cylinders by the original surface and the measurements indicate that the cylinder is within 0.002 in. of the original size. The results of this application are not yet available. However, it will be watched with particular interest, inasmuch as it has to contend with elevated temperatures as well as abrasion. The fact that chromium is particularly resistant to chemical action of the fuel oil may also provide some data in connection with the "corrosion theory" which is being discussed so extensively.

FIG. 7 PITTING ON THE WATER SIDE OF A CYLINDER LINER

In addition to harder wearing surfaces resulting from the various reconditioning methods which have been used on mild- and tempered-steel cylinders, some very interesting information pertaining to the use of cast iron and nitrided steel for this purpose has been developed on these engines.

In the application of cast iron in place of steel, it has been necessary to reduce the cylinder size somewhat in order to provide sufficient strength, and this may have had an influence on the results. We have been unable to find a great difference in rate of wear on nickel iron, ordinary gray iron, or iron cast centrifugally. Any of them, however, appear to wear only about half as rapidly as mild steel. The greatest difficulty with the use of this metal on these particular engines, which were designed for steel cylinders, is in the application within the narrow confines of the crankcase.

Cylinders of nitralloy steel are giving a very creditable performance. Tests have been carried out over 259,000 miles in obtaining comparisons. These indicate that the maximum wear is 0.007 in. in 80,000 miles, which is only about one fourth to one fifth the amount on mild steel in similar service. The attempts which have been made to reclaim any cylinders of this material are unprofitable because of the difficulty in grinding the excessively hard surface. Also the second wear is inferior because the surface hardness is removed.

The pitting of the steel cylinders, as a result of the action of the cooling water on the outside, is also a problem which has been dealt with in maintenance. Fig. 7 shows an example of this condition. Zinc and aluminum spraying of some of the cylinders has been used to prevent this action in order to continue the cylinders in service for a longer period. A certain amount of pitting occurs at all times, but usually the cylinder is worn to the limits mentioned before serious weakness results. A limit of $^5/_{32}$ in. wall thickness, measured at the bottom of the deepest pit, has been set up for steel cylinders in order to avoid this condition. All liners are coated with a corrosion-resisting paint during manufacture or reconditioning to counteract the attack of the cooling water. No trouble whatever has been experienced with pitting on cast-iron or nitrided cylinders.

PISTONS

Of the various wearing parts of these engines, the pistons present the most complex problem, and have been the subject of considerable study both as to design and maintenance. The almost continuous variation in speed and load over wide ranges, which has to be dealt with in railway traction, makes greater demands on the piston than most services. Further, the introduction of aluminum-alloy pistons, so essential to these high-speed, lightweight engines has tended toward higher lubricating-oil consumption—first, because of the varying clearances between the piston and cylinder resulting from the previously mentioned service requirements; and, second, because the comparatively soft aluminum alloy wears more rapidly than other piston materials.

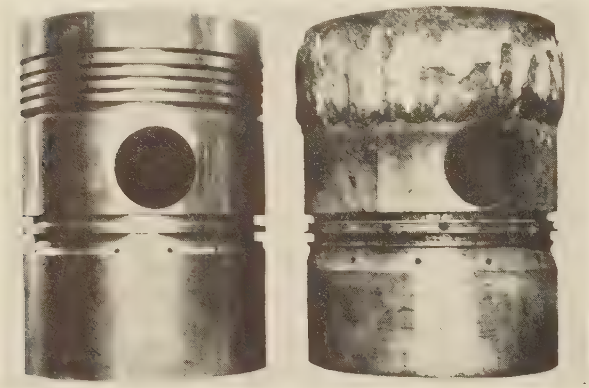
Considerable painstaking work and time have been necessary in developing maintenance methods to meet these conditions. However, a very satisfactory reduction in lubricating-oil consumption and reconditioning these parts has followed our efforts and we have been enjoying the benefits for several years.

Of the sand-cast, die-cast, and forged-aluminum pistons which have been employed since 1925, the forged metal is most suitable, as it is stronger, more ductile and wear-resistant. It is more expensive, however, because of the more costly process of manufacturing the metal and machining this part from the solid forging.

Wear of the ring grooves in any of the alloy pistons appeared as a difficulty early in the operation of these engines. It was, in fact, this item which determined their useful life. In bringing this factor within reasonable limits, it has been neccessary to consider the effect of the fuel oil as well as the design and metal from which the pistons are manufactured. In the early days, fuel specifications were written in broad terms to take care of the very wide territory in which these engines operated. However, it seems that two fuels can have apparently identical physical characteristics and yet the reaction on the piston from a wear standpoint may be widely different. Improved fuel specifications, which have been developed, and the adoption of narrower and diametrically thicker rings proved helpful. However, there was still the necessity for reconditioning the ring grooves. Wear on the top grooves has been limited to 0.006 in. and when this is exceeded the grooves are machined out to take overwidth rings. It has been proved that good piston rings in equally good grooves are steps in the right direction, and much of our effort has been directed toward this end.

Engines such as these, designed with minimum weight, of necessity have the wrist-pin hole somewhat above the center of the piston, which has a very limiting effect on the width of the lands between the piston rings. This restriction does not allow for much widening of the groove until the land is altogether too weak and subject to breakage. We have, therefore, limited this feature of our reclaiming operations to 0.025 in.

over standard width. The rate of wear on the ring lands remained so much greater than that occurring on the rubbing surfaces of the piston or wrist-pin hole that there are many pistons which could be used further provided the original condition could be regained at the ring belt. To accomplish this, acetylene welding is being employed and, in Fig. 8, at the right, is shown a piston which has had the entire ring belt machined off and new metal deposited by this method. At the left appears a similar piston after heat-treatment and machining. In the investigation prior to the adoption of this method, sand-cast and die-cast pistons were examined both before and after welding, and some of the results are shown in Fig. 9. This shows an enlarged section of an unwelded piston located in this work. This particular one is somewhat worse than average regarding porosity. Also in Fig. 10 is shown a section illustrating a welded piston, for comparison. This enlargement shows the condition of the welded ring belt after machining. It will be noted that the porosity even in the newly deposited lands is not



After Machining Before Machining

Fig. 8 Pistons Reclaimed by Acetylene Welding

nearly as serious as in the original casting shown in Fig. 9. The strength of original and welded lands on pistons was determined by the load required to break them off one at a time. Typical loads required to break lands off an original piston are 35,000, 36,000, and 35,500 lb while typical loads for a welded piston are 60,000, 66,000, and 64,500 lb.

It was thus observed that the deposited metal was considerably stronger than the original, and resulted in the employment of this method in lengthening the service of the pistons that were in good condition in other respects. Several trials were necessary to learn the proper heat-treatment for the various alloys, but, once this was understood, it was carried out in routine manner very successfully. Examination of the deposited metal indicated that it was not exactly the same as the piston material, although the welding rods were of similar composition before they were used. Apparently some change takes place during the process.

The file marks on the weld, shown in Fig. 8, are the result of taking samples for analysis. The machining of the outside diameters has been treated in line with that described for the cylinders. The welded pistons are always machined down 0.025 in. in diameter which removes any distortion caused during the welding process. The wrist-pin holes were found to close in slightly under this treatment and this is an advantage, since it permits the wrist pin to be refitted to standard clearances.

In connection with newly manufactured pistons of 8 to 12 in. diameter, it has been demonstrated repeatedly that a certain amount of distortion takes place soon after they are placed in service, and, in connection with reconditioned parts, this does not seem to be so noticeable. In the ordinary course of events, pistons which have been reconditioned after 75,000 miles have

NOTES

F = Front nearest to gear case
R = Rear
V = In vertical plane
H = In horizontal plane
Difference between V and H indicates ovality and should be zero.
Difference between F and R indicates taper and should not exceed .002 in.

When being measured the crankpin to be on T.D.C.

If serious ovality is found on main journals, the measurements shall be recorded in relation to a T.D.C.

Recorded at: Winnipeg, Man.
Recorded by: Geo. F. Shaw

FIG. 11 FORM FOR RECORDING RATE OF CRANKSHAFT WEAR

been fitted with smaller clearances without any evidence of seizure.

CRANKSHAFTS

Diesel-engine crankshafts are handled in a manner similar to the pistons and liners in regard to records of wear and sizes. In Fig. 11 is shown a copy of this form which is typical of the wear occurring on this part. In some studies made several years ago comparisons were made between nickel, chrome-nickel, and carbon steels for wear resistance, and it was found that there was very little choice between them. However, in replacement, the trend has been toward alloy steels because of the harder bearing surfaces and greater strength. On main journals, the wear varies between one and two thousandths on diameter in 100,000 miles and the crankpins show six to nine thousandths during this period on the usual run of crankshaft steel.

The Nitralloy crankshafts which were applied several years ago are standing up remarkably well, and, on the average, indicate the wear to be about one sixth that usually found. In practically every instance, regardless of the type of steel, however, the crankpin wear is four to five times that found on the main journals. In reconditioning crankshafts the practice is to turn the crankpin and journal which is in the worst condition first, and then use the size which has been thus established for the remaining pins and journals. In this way it is not found necessary to establish definite undersizes for this part, and in a measure this has extended the life of the shafts, as only sufficient metal is removed to true them up. Very good results have been obtained with a Webber tool in turning crankpins. This tool is one of the type which is used in the lathe and follows the crankpin around in its normal path when revolving on the main journal centers. Any pins which are oval are first filed to make them round so that the tool will be guided by a fairly true surface throughout the entire operation. Wooden polishing blocks are employed and fine abrasive compounds are used in the final finishing, producing accuracy in line with manufacturers' tolerances.

A crankshaft from one of the six-cylinder engines, which is about 9 ft long, is shown in Fig. 12. This has the main journals and crankpins chromium-plated with the object of lowering the rate of wear. The sizes were increased 0.010 in. which, although not regaining the original size, is thought to be sufficient to prolong the life of the shaft for a considerable period. The tolerance of the plate itself was kept within one-half thousandth, which is very creditable for such a large article. There has not been sufficient service on this shaft as yet to indicate any wear. However, as the hardness is in line with nitriding, it is expected that the rate of wear will be very low.

CONNECTING-ROD CRANK BEARINGS

One of the problems which developed in the early use of these engines, and for which the maintenance staff was obliged to find a solution, related to crank-bearing failures. This amounted to cracking of the babbitt lining in the rod or top half of the bearing which continued until most of the babbitt in the high-pressure area was loose and broken in small pieces. If this condition was not detected, the detached pieces pounded out until they interfered with lubrication, causing heating, or the bearing shell came down on the crankpin. It was found that it did not take long for most of the babbitt to become loose after the initial crack had formed and it was not unusual for loose babbitt to go unnoticed until the bearing was removed for inspection. The loose pieces would, of course, fall out when the bearing was disturbed, and renewal was necessary. Cracking never occurred in the bottom half of the bearing and the main bearings also were practically trouble free. The fact that the babbitt metal employed included all the popular tin-base alloys and from failures which occurred with several of these which were applied under expert supervision, there was a strong belief that

the loads were too high. To offset this, however, a study of the records indicated that some bearings operated in excess of 200,000 miles without renewal. These, of course, were rather exceptional in the early days. However, these rare occurrences indicated the direction of improvement, and final solution of the problem followed.

Flexing of the bottom end of the connecting rods was given attention and, in later installations, bearing sizes were increased and the rods strengthened. An idea of the extent of this alteration can be gained from Fig. 13 which indicates the differences in weight. However, the trouble continued and, at one stage

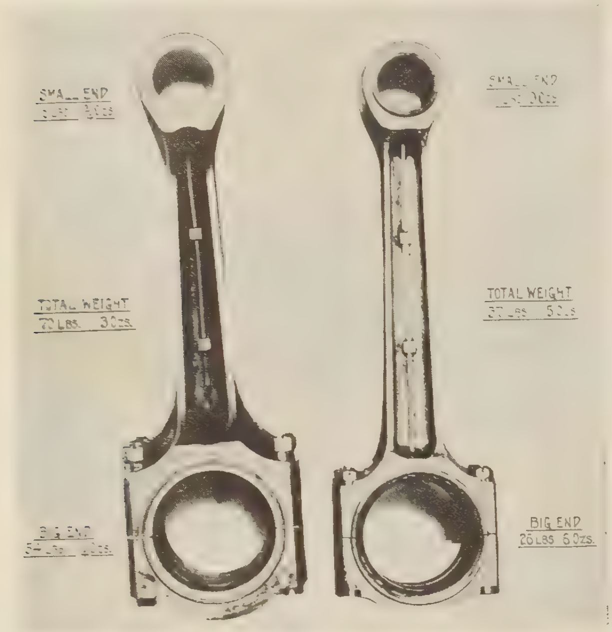

Fig. 13 Comparison of Connecting Rods Before and After Increasing Strength and Bearing Sizes

of the investigation, several methods of babbitting the crank bearings were tried. These included babbitting direct on the steel rods without the use of shells, and the use of bronze-lead combinations which were only partially successful. The experience which was gained resulted in some very definite ideas regarding the best type of crank bearing for railway traction.

Protection of the crankshaft against damage under severe and abusive conditions is an important factor because passenger trains must be on time if humanly possible. This means that under abnormal conditions an engine may be operated without a proper supply of lubricating oil, with disastrous results. The development of a crank-bearing shell which can be operated after the babbitt has disappeared without damaging the shaft is the answer. The use of a shell of this type which can be easily removed for inspection or replacement, has permitted reasonable maintenance and provided good protection for the crankshaft.

As a consequence of the poor results obtained with the bearings in the early days and the time required to obtain replacements and deliver them to remote parts of the railway system, attempts were made to manufacture bearings in the railway shops. At first these were not very successful, but by the use of special babbitt with high lead content, together with improved practice regarding its application, the crank bearings have ceased to be a troublesome feature in maintenance. Lead is usually thought of as an extremely soft and ductile metal. However, the addition

TABLE 3 ANALYSIS OF BEARING MATERIAL

Element	Babbitt, per cent	Lead-bronze, per cent
Copper	1.00	77
Lead	78.75	15
Tin	1.25	8
Antimony	18.00	
Arsenic	1.00	

of antimony and arsenic gives it a surprising hardness without interfering with its antifriction qualities.

Bronze shells with a phosphorus content were also found to be unsuitable and the best results are being obtained with babbitt, and shells of the composition given in Table 3. The jig which is employed is made solid in order to retain the heat and it is kept between temperatures of 250 and 300 F. The tinning bath is composed of babbitt containing 70 per cent tin and 30 per cent lead solder, maintained between temperatures of 600 and 650 F. Considerable care is exercised in maintaining the babbitt pot at 1050 F, and the molten metal is poured from a ladle previously raised to the same temperature. This ladle is of a large size enabling a complete pour to be made in one operation. The shell is not removed from the jig until it has cooled to 225 F.

During the tinning process the shell is completely immersed in the bath and left until it has reached a uniform temperature, being removed to coat it with soldering flux. This, briefly, is

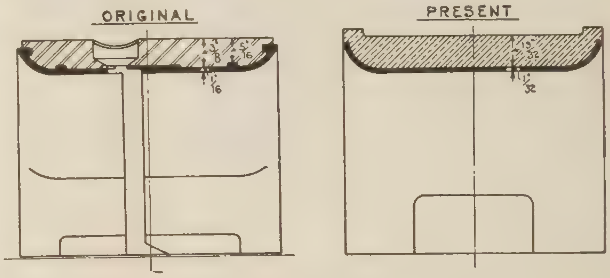

Fig. 14 Changes in Design of Connecting-Rod Crank Bearings Which Has Increased the Service Life of the Bearings

Diameter of crankpin, in.	4.75

the practice employed during the process and great care is exercised to insure cleanliness and accuracy.

The rough hammer-and-chisel maintenance methods credited to the railway organization no doubt caused unnecessary failures, but this same method applied to the babbitt of the big-end bearing resulted in a test definitely proving the degree of adherence between the babbitt and shell. When this chipping test showed that there was no tendency for the babbitt to peel away from the shell, an almost perfect bond existed between the two metals. The feature since that time has been only the reproduction of the conditions under which this satisfactory bonding occurred, and in this respect the human element plays an important part. There is now only an occasional bearing which shows trouble on inspection, and the average life of these is well above 100,000 miles. Most of the engines go from shopping to shopping without renewal.

In the manufacture of bearings, certain slight changes were found beneficial. These are illustrated in Fig. 14 and show the details of a bearing which was one of the worst offenders, together with particulars of the working conditions. Fig. 14

TABLE 4 MAINTENANCE PRACTICE FOR DIESEL-ENGINE PARTS

Part	Limits of wear	Average mileage	Type of repairs
Crankshaft	0.006 in. out-of-round on two or more crankpins	250,000	Recondition
Cylinders	Worn between 0.045 and 0.060 in. on diameter	150,000	Recondition
Pistons	Worn 0.010 in. above top ring; 0.006 in. clearance in three ring grooves; 0.005 in. clearance in wrist-pin hole	100,000	Recondition
Connecting-rod bearings	Clearance maintained between 0.003 in. and 0.004i n. by adjustment of shims	No record of worn-out bearings	
Wrist pins	Worn 0.006 in. on diameter	300,000	Renew
Exhaust valve	Renew when bent, warped, or stem worn 0.005 in.	75,000 200,000	Grind Renew
Exhaust-valve guide	Renew when worn 0.008 in.	100,000	Renew
Piston rings	Gap opening increased to $^1/_8$ in.	75,000	Renew

shows the original design and the improvement which has been in successful operation for several years. Anchor grooves and oil grooves were eliminated and the babbitt thickness has been materially reduced. Oil pockets were cut at right angles to the rod center line and end collars have been added.

Bearings of $4^3/_4$ to 5 in. diameter are installed with only 0.001 to 0.002 in. clearance, and operate at normal temperatures with clearances of 0.003 in.

General

A certain amount of distortion is found in the main-bearing openings of the crankcases after several years of service. However, the practice of line reaming the main bearings in place which has been adopted, takes care of this. The slight differences in babbitt thickness which results from this practice is of no consequence. The same type of bearing is used in the mains as in the connecting rods previously described. Extremely long life is obtained from these. However, in the ordinary course of events they are renewed at each general overhaul when the crankshaft is reconditioned. In other words, these bearings do not wear out but are replaced with bearings of smaller size to accommodate the reconditioned shaft.

The reconditioning of aluminum cylinder heads with steel valve seats has presented no problems uncommon to automobile engines. Occasionally a head will become cracked and, excepting when this occurs in the combustion-pressure area, it is repaired by welding. A 50-lb hydraulic test of the water space is made following such repairs. Reaming of the seats is required at periods of 100,000 miles. Exhaust-valve guides also require renewal at this period.

The four-cylinder engines have been practically free from any renewal of parts in the gear cases in spite of mileages around 500,000. On the six-cylinder engines, however, this unit becomes noisy at about 150,000 miles and will require renewal of gear-case parts at 200,000 miles. It is likely that the difference in torsional vibration is responsible for this, and on some occasions it has been noted that early trouble with the gears was associated with an improperly adjusted vibration damper.

The type of wrist pin with which these engines are fitted, which is free to revolve both in the piston and the bearing, is very easy to maintain. It is only in the last few years that they have required any attention. Wear of 0.006 in. is the maximum which has been found even after many years operation. This is rather surprising as the loads on this part are high. The wear on wrist-pin bosses in the piston and also in the rod bushing is relatively low, and the only measure which has been taken to regain the original clearances on worn parts is in providing 0.005 in. oversize pins by means of chromium plating.

Fuel-injection pumps and atomizers are sent in to a central repair shop which is adjacent to a toolroom equipped to make adequate repairs. Plungers and valves are reduced in diameter 0.003 and 0.005 in. as required, and new bushings are fitted. Considerable technique has been developed in this work, and lapping of the parts which at one time was a tedious job has been cut to a minimum. Each pump unit is given a static test of 5000 lb pressure as an initial check for leakage. The completed pump is put on an operating test and the fuel quantities balanced using the atomizers which are to be installed with it.

Governors, lubricating-oil pumps, water pumps, and primary fuel-oil pumps operate over 200,000 miles between shopping

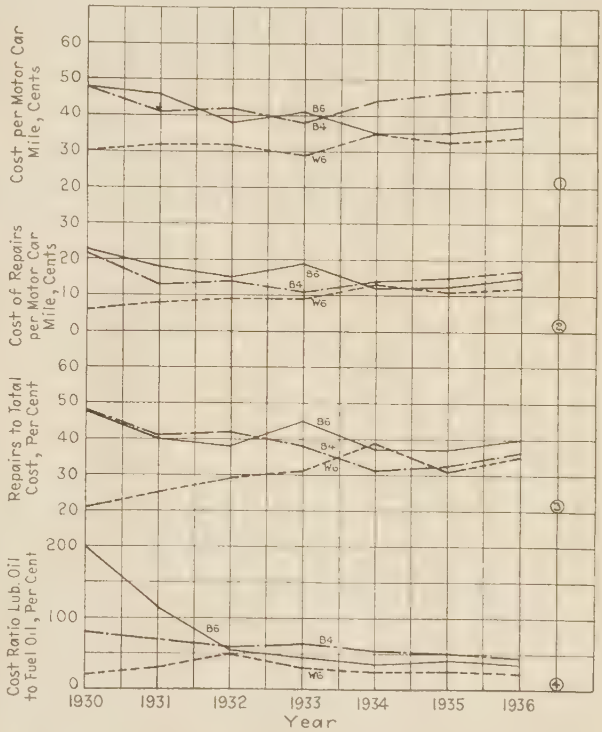

FIG. 15 COST PER CAR MILE FOR DIESEL-ENGINE OPERATION

AVERAGE DAILY MILES PER ENGINE

Year	Miles	Year	Miles
1929	220	1933	185
1930	206	1934	184
1931	191	1935	191
1932	180	1936	181

periods without trouble. Often these will go to the third general overhaul before requiring much attention. Two or three spare units of each type have been provided for protection and are handled similarly to pistons and liners, being repaired at a central shop and sent to outlying repair points as occasion demands.

Some further impressions of the average mileage which is being obtained from various engine parts under the maintenance practices which have been described are shown in Table 4. This also shows data relating to the limits of wear which are in effect.

Further details of the more important factors pertaining to the cost of maintenance are included in Fig. 15 for years 1930–1936. The average trend of total cost per mile, shown in curve 1, has been downward to 1934 and has held between 36 and 40 cents per mile since then. One of the greatest influences on total cost is total miles and, unfortunately, as a result of alterations in train schedules, the runs which have been operated by this equipment are shorter than previously. At one time groups of these cars were on runs of 300 miles per day and this dropped to

220 miles in 1929 and has made a further drop of 13 per cent since. The fact that repair cost has held constant, or been slightly lowered, as shown in curve 2, in spite of this, is very gratifying. It has been impossible to obtain the cost of engine repairs separate from the other mechanical and electrical repairs. However, the fact that there has been a general improvement in this is seen from curve 3, which gives the repairs in per cent of total cost. Last, but not least, in curve 4 is shown the very satisfactory reduction in lubricating-oil consumption which has resulted from a systematic handling of pistons and cylinder-liner repairs.

Some ideas on depreciation of Diesel-engine equipment can be gained from our experience. In the first place the results after 12 years with the oldest engines indicate that an estimated life of 20 years is conservative. The possibility of engines of this type becoming obsolete or the costs rising to where they are uneconomical after extended service is remote. By inexpensive investigation, it is possible during overhaul to improve and modernize the engines, even within the narrow confines of existing crankcases, with beneficial results. Finally, by careful records of wear being kept, a systematic handling of repairs can be set up which results in a lowering and stabilizing of engine-repair costs. Up to the present it would appear that depreciation is practically taken care of by renewal of the active parts.

Resistance of Lightweight Passenger Trains

By A. I. TOTTEN,[1] ERIE, PA.

The author discusses the factors affecting the resistance of modern lightweight streamlined trains, using the fundamental data collected by different authors, and presents them in a more practical form than heretofore available. These factors include those due to track and journal resistance, flange resistance, and air resistance, as well as the resistance offered by natural or ground winds and by the installation of air-conditioning and lighting equipment on the cars. The author gives formulas for calculating such resistances, and includes in the paper examples showing how to apply the formulas.

FOR MANY years there was little information available in a concrete form, for the guidance of transportation engineers, in the matter of tractive resistance of locomotives and cars of various types and weights. Antedating that time, however, Schmidt and Dunn[2] at the University of Illinois, the Pennsylvania Railroad, and the General Electric Company had obtained considerable experimental data which were directly applicable only to certain specific conditions.

About ten years ago W. J. Davis, an engineer of the General Electric Company, correlated the various sources of information and issued a treatise[3] which subsequently became, throughout the world, the recognized authority on this most important subject. Although Davis' formulas related specifically to electric locomotives, nevertheless they are susceptible of application to steam engines by segregating the losses peculiar to this type of motive power.

Recent years have produced rolling-stock developments, especially in the case of passenger equipment, which, although in some measure visualized by Davis, were not embraced in the formulas and curves, which covered in detail practically all forms of the then existent motive power and cars.

[1] Transportation Department, General Electric Company. Mr. Totten began his railroad career in 1900 with the Southern Railway. He was then appointed electrical engineer of the Queen and Crescent Railway at Cincinnati, Ohio, and later became engineer of shops for the Southern Railway, and then electrical engineer for the Seaboard Air Line Railway. After leaving this position he spent several year with the General Electric Company in the study of the requirements of shop equipment of the various steam railroads. He then accepted a position as electrical engineer and assistant superintendent of motive power with the Brazil Railway, with headquarters at Sao Paulo, Brazil. Returning to the United States as expert appraiser of special railroad franchises for the New York State Tax Commission, he rejoined the General Electric Company in 1918. Since that time he has made exhaustive studies connected with the application of electric power and Diesel-electric equipment to steam-railroad operation. He is a member of the American Institute of Electrical Engineers, and has contributed numerous papers and articles to the technical press.

[2] "Passenger-Train Resistance," by E. C. Schmidt and H. H. Dunn, Engineering Experiment Station, Bulletin No. 110, University of Illinois, Urbana, Ill.

[3] "The Traction Resistance of Electric Locomotives and Cars," by W. J. Davis, Jr., *General Electric Review*, October, 1926, pp. 685–707.

Contributed by the Railroad Division for presentation at the Semi-Annual Meeting of The American Society of Mechanical Engineers, to be held in Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Rapid progress along the lines of lightweight, streamlined, and articulated equipment, appears to make essential the derivation of new methods of approach for the determination of tractive resistance factors, upon which must be based all calculations pertaining to train time schedules, power-plant capacity and fuel consumption for modern railroad service.

It is the intention of the author to draw freely from Davis' valuable contributions[3] on the general subject and also from the paper by DeBell and Lipetz[4] which deals specifically with air-resistance components. As a matter of fact, it is not the intent to introduce any new fundamental data in this paper, but to merely condense into more practical form, for universal application, the researches of other engineers along the lines in question.

There appears to be no reason for departing from Davis' original segregation of train-resistance factors, which may be summarized as follows:

(*a*) Those that are constant with respect to speed, R_1.
(*b*) Those that vary as the first power of the speed, R_2.
(*c*) Those that vary as the square of the speed, R_3.

For convenience in discussion, these three factors will be separately treated under the following subjects.

Track and Journal Resistance

According to the Davis formulas, these elements are covered by a fixed and a variable component, the latter being inversely affected by individual axle loadings. Based upon Schmidt's[2] experiments these factors were expressed as

$$\text{Unit resistance per ton} = 1.5 + (100/W)$$

where W represents the entire weight in tons on four axles. The modification in the Davis formulas shows

$$\text{Unit resistance per ton} = 1.3 + (29/w)$$

where w represents the weight per axle in tons. The differential, as between these authorities, results in the following:

$$\text{60-ton car}\begin{cases}\text{Schmidt } 1.5 + \dfrac{100}{60} = 3.17 \text{ lb per ton}\\[2ex] \text{Davis } \quad 1.3 + \dfrac{29}{15} = 3.23 \text{ lb per ton}\end{cases}$$

$$\text{30-ton car}\begin{cases}\text{Schmidt } 1.5 + \dfrac{100}{30} = 4.83 \text{ lb per ton}\\[2ex] \text{Davis } \quad 1.3 + \dfrac{29}{7.5} = 5.17 \text{ lb per ton}\end{cases}$$

Thus, the unit resistance, as between the two formulas shows decreases of the order of 34.5 to 37.5 per cent for an increase in the car weight of 100 per cent.

Apparently no attempt has been made to segregate the components of rolling resistance, track resistance, and journal friction, although it would appear that the value of journal friction might be established independently of the other elements, through the medium of stand tests. Furthermore, it seems, that while the unit of journal resistance will vary more or less inversely with

[4] "Air-Resistance of Passenger Trains," by G. W. DeBell and A. I. Lipetz, *Railway Mechanical Engineer*, vol. 109, December, 1935, pp. 496–501.

the weight per axle, the rolling resistance, for a given rail weight, will vary to some extent directly with the axle loading.

The tendency is ever prevalent toward larger rail sections, and the lightweight equipment, now under discussion, has materially lower axle loadings and consequently wheel pressures. Both of these elements act in the same direction, pointing to a decrease in track resistance occasioned by the so-called "wave action." This feature is emphasized in tests on the Kansas City Southern Railway,[5] conducted in 1930, which showed a reduction of 0.4 lb per ton with identical axle loadings, but with the rail weight increased from 84 to 150 lb per yard.

These mentioned tests[5] indicate a resistance decrease of 0.1 lb per ton for a rail-weight increase of 19.7 per cent, consequently it may be reasonably assumed, that a corresponding reduction in axle loading, with a constant rail weight, will produce similar results.

The tendency in lightweight equipment indicates a reduction in unit axle loading of about 17 per cent for locomotives and from 12 to 25 per cent for cars to operate on existing tracks. While it would therefore seem proper to make some reduction in the first group of the Davis formulas for the reasons herein cited, it is not believed that the information at hand is sufficiently conclusive to warrant such action.

The advent of roller journal bearings on rolling stock does not appear to have a material effect on the resistance units involved, although it is fully recognized that the initial starting resistance is thereby reduced materially as compared to A. A. R. brass journal bearings. Some opinions and tests controvert this statement.

One roller-bearing company presents laboratory tests, which show a decided uniformity of resistance for roller bearings, which is irrespective of speed and with values of one third to one sixth of those applying to journal brasses.

Another roller-bearing manufacturer estimates a decrease in resistance for roller bearings of 80 per cent at starting, 25 per cent at 15 mph, and 33 per cent at 75 mph, as compared to journal brasses.

Certain tests, made by the Chicago, Milwaukee, St. Paul, and Pacific Railroad indicated an overall differential of 0.6 lb per ton in favor of roller bearings for 80-ton six-axle cars at a speed of 10 mph. This constitutes a decrease of 17 per cent from the components normally applied, under like conditions, to brass journal bearings.

The Budd Manufacturing Company estimates a reduction of 20 per cent in journal friction for roller bearings, presumably under high-speed operating conditions.

The experience of other manufacturers, which is supported by Pennsylvania Railroad and Illinois Central Railroad tests, does not indicate, that at normal operating speeds, there is any pronounced difference in resistance values for the two classes of bearings under discussion.

After giving due consideration to all of the foregoing and pending more definite information on the subject, it is decided to maintain the Davis factor as uniformly applicable to both roller bearings and journal brasses. The final components for R_1 thus become

$$R_1 = 1.3 + \frac{29}{w} \quad [1]$$

where w = weight per axle in tons.

Flange Resistance

The term "flange resistance" shall include all forms of resistance proportional to the first power of the speed. These also embrace, in general, flange friction, resistance elements due to concussion, swaying, and oscillation. It is obvious, that the character of track construction, truck-wheel spacing, the use of truck restraining devices, and other items of lesser import are controlling factors in the constant to be employed.

In Davis' analysis of this problem there are established constant values varying from 0.03 to 0.09 depending upon the type of service considered. These constants are as follows:

Locomotives (electric)	0.030
Passenger cars (4 or 6 axle)	0.030
Freight cars (4 or 6 axle)	0.045
Multiple-unit cars (4 axle)	0.045
Interurban cars (operated singly)	0.090

The high value of 0.09 was used only for single car operation, where oscillations, etc., are naturally magnified without the restraining influence exercised by a connected train.

The lightweight high-speed equipment considered in this analysis will consist of locomotives or power units weighing from 75 to 250 tons in combination with lightweight four-axle or articulated cars.

There is no question but that the locomotives or power units should be placed in the category where the 0.03 constant applies. The relatively lightweight trailing cars will have comparatively short truck-axle centers. As an offsetting feature, however, the highest grade type of construction, probably with truck-stabilizing features, is employed. In addition, high-speed operation is of necessity conducted over a well-maintained right of way, with the resultant oscillating features held to a minimum. Furthermore, the recent practice of flat turning the tire treads gives every indication of materially reducing flange contact and pressure on the rail head when operating on tangent track.

For all of the reasons cited in the foregoing paragraph, it is decided to maintain the present minimum factor for both locomotives or power units and the trailing cars. The constant therefore remains as

$$R_2 = 0.03\,V \quad [2]$$

where V = speed, mph.

Air Resistance

Air resistance, in effect, covers not only head-end resistance but all air elements, including those pertaining to such factors as turbulent or eddy currents, skin friction, ground wind, and viscous drag. It is generally assumed that such resistance varies as the square of the speed which, while not entirely true, is sufficiently accurate for all practical purposes.

The Davis formulas apparently took cognizance of the fact that a more or less definite relationship existed between the cross section, weight, and length of the individual car units, which accorded automatic compensation for skin effects. Thus, he used the head-end area in combination with a proper constant for establishing total air resistance and divided the resultant, so derived, by the weight of each individual car or locomotive for the purpose of obtaining the unit resistance expressed as pounds per ton.

The later use of aluminum and high-tensile steel alloys, disturbed the previously mentioned equilibrium so that the principal authorities on this particular subject now deem it best to take the cross-sectional area or perimeter of the locomotives or cars, in combination with the length, for securing total air-resistance values.

Streamline effects were considered by Davis,[3] but not extended to the formulas or curves in which his studies culminated. Based upon tests made in St. Louis by the Electric Railway Test Commission, he established the following coefficient per-

[5] "What is the Economic Weight of Rail," *Railway Age*, vol. 88, May 24, 1930, pp. 1231–1237.

centages for the body only, with different forms of vestibule constructions, which presumably applied to both ends of the individual car as tested. These are as follows:

Flat	100 per cent
Standard (truncated wedge)	67 per cent
Parabolic	35 per cent
Parabolic wedge	33 per cent

It was ascertained that the single car, used in the previously mentioned St. Louis tests, produced a coefficient of air resistance of 0.00228, which was magnified to 0.0024 in the Davis formulas. If the ends of the car had been of parabolic shape, but without other changes, then the coefficient as applied to the head-end cross-section and the V^2, would become 0.001495.

In recent years, through the medium of wind-tunnel tests, considerable data have been collected, especially for airplanes and streamline-train resistances which are of value in the determination of R_3 or the third factor of the train-resistance formula. This whole subject is well presented by DeBell and A. Lipetz,[4] and by Ober.[6]

It is obvious, that the selected shape of the head and rear end of the train, as well as many other details of design, which may be influenced by factors other than those attributable solely to air-resistance features, will have some effect on the final resistance units that will apply. These variables are represented by the symbol K in formulas to follow. Open-skirt construction (18 in. from skirt to top of rail) or closed-skirt construction, where the entire underframing is shrouded, are elements which must also be considered. The relative constants for these last two alternative methods of construction on power cars, as defined by DeBell and Lipetz,[4] is 0.00224 for open skirts, 0.002 for closed skirts; the decrease for closed skirts is therefore 0.00024 or 10.75 per cent.

The K factors, as ascertained from the tests, are as follows:

K_1 = For power or leading-car nose well streamlined = 0
For nose bluntly streamlined = 0.000036 × cross-sectional area of nose at full section, including trucks, in square feet

K_2 = For tail shape of rear car well streamlined = 0
For tail bluntly streamlined = 0.000061 × cross-sectional area of tail at full section, including trucks, in square feet

K_3 = For power-car trucks, both faired = 0
For unfaired trucks = 0.00026

K_4 = For faired trailing-car trucks = 0
For unfaired trucks = 0.00013 × number of trailing-car trucks

K_5 = For smooth diaphragms = 0
For cowled diaphragms = 0.000037 × P_c × number of diaphragms

K_6 = For no bulge of power car = 0
For bulge of good streamline shape = 0.00032 × cross-sectional area of bulge in square feet
For bulge of relatively poor streamline shape = 0.00051 × cross-sectional area of bulge in square feet

K_7 = For closed wheel shrouds on streamlined locomotives (all wheels completely enclosed) = 0
For open shrouds (2 ft × 2 ft 6 in. inspection openings over the driving-wheel journals) = 0.0005 × total number of openings
For short shrouds (driving wheels and tender trucks completely exposed) = 0.0182

K_8 = For helmet nose on streamlined locomotive = 0
For straight nose = 0.0021
For round nose = 0.0026

K_9 = For round-top boiler shape on streamlined locomotive = 0.
For cowled top (domes and fittings enclosed in longitudinal cowl above boiler shroud) = 0.0035

For the purpose of this analysis and in order to present some examples showing the adaptation of the DeBell and Lipetz[4] formulas, the following three basic types of equipment are selected:

1 The streamlined locomotive-hauled train with open-skirt streamlined cars, having (*a*) no adverse design elements and (*b*) maximum adverse design elements.

2 The streamlined locomotive-hauled train with standard cars, having (*a*) no adverse locomotive-design elements and (*b*) maximum adverse locomotive-design elements.

3 The streamlined power-unit articulated train with closed skirts, having (*a*) no adverse design elements and (*b*) maximum adverse design elements.

For the first case, a streamlined electric, Diesel-electric, or steam locomotive with a train of lightweight streamlined cars is assumed. The simplified formula, as established by DeBell and Lipetz,[4] is

$$R_3 = (0.023\sqrt[3]{L_L} + K_L) + \left[0.001735P_c\left(\frac{L_c}{100}\right)^{0.88} + K_c\right]V^2 \qquad \text{[3]}$$

where L = length of train, ft; L_L = length of locomotive or locomotive and tender, ft; L_c = length of car consist (rear of locomotive or tender to rear of train), ft; P_c = perimeter of cars from plane of top of rails over car to plane of top of rails, ft; and K_L and K_c = constants based upon details of construction.

The constants for the locomotive resistance presuppose a cross-sectional area equivalent to that of the New York Central Hudson-type steam locomotive which is a fair average for all locomotives considered for the particular type of service now analyzed. The individual formula for the locomotive, reduced to a unit basis, expressed in pounds per ton is

$$R_3 = \frac{(0.023\sqrt[3]{L_L} + K_L)V^2}{W} \qquad \text{[4]}$$

and for the cars (14 ft high from top of rail to roof, 10 ft wide, and with an effective perimeter of 40 ft), expressed in pounds per ton is

$$R_3 = \frac{\left[0.0694 \times \left(\frac{L_c}{100}\right)^{0.88} + K\right]V^2}{W} \qquad \text{[5]}$$

where W = total weight of locomotive or cars, tons.

For the second case a streamlined electric, Diesel-electric or steam locomotive with a train of standard vestibuled cars is assumed. The simplified formula is

$$R_3 = (0.023\sqrt[3]{L_L} + K_L) + \left[0.0031 \times P_c\left(\frac{L_c}{100}\right)^{0.7} + K_c\right]V^2 \qquad \text{[6]}$$

The locomotive formula for unit resistance remains as in the first case, that is, Equation [5].

The following substitution, expressed in pounds per ton applies to the cars

$$R_3 = \frac{\left[0.124\left(\frac{L_c}{100}\right)^{0.7} + K\right]V^2}{W} \qquad \text{[7]}$$

---

[6] "Air Resistance of the Burlington 'Zephyr,'" by S. Ober, *Railway Gazette*, Supplement, June 14, 1935, p. 1184.

For case No. 3, the train hauled with a power unit is treated as a whole upon the basis of the formula

$$R_3 \left[0.0020\, P_c \left(\frac{L}{100}\right)^{0.8} + K \right] V^2 \ldots\ldots\ldots\ldots [8]$$

The cross-section areas for trains of this character are somewhat less than that for the locomotive-hauled trains previously considered. The distance from top of rail to roof is now taken as 12 ft and the width as $9^1/_2$ ft, thus producing a perimeter of 35 ft. On this basis the unit formula expressed in pounds per ton, may be simplified somewhat as

$$R_3 = \frac{\left[0.07 \left(\frac{L}{100}\right)^{0.8} + K \right] V^2}{W} \ldots\ldots\ldots\ldots [9]$$

The application of the suggested formulas to hypothetical train compositions is shown as follows, based upon certain assumptions, as defined along the lines of recent developments.

Example—Case No. 1

Consider a locomotive with a weight of 200 tons, a length of 80 ft, and eight axles. The train consists of ten 50-ton, 70-ft cars with four axles per car, assume a train speed of 90 mph.

Ideal Design. The resistance of the locomotive is

$$R = 1.30 + \frac{29}{w} + 0.03\, V + \frac{(0.023\, \sqrt[3]{L_L} + K)V^2}{W}$$

$$= 1.30 + 1.16 + 2.70 + \frac{(0.023 \times 4.3 \times 8100)}{200}$$

$$= 9.17 \text{ lb per ton}$$

The resistance of the cars is

$$R = 1.30 + \frac{29}{w} + 0.03\, V + \frac{\left[0.0694 \left(\frac{L_c}{100}\right)^{0.88} + K \right] V^2}{W}$$

$$= 1.30 + 2.32 + 2.70 + \frac{(0.0694 \times 5.54 \times 8100)}{500}$$

$$= 12.55 \text{ lb per ton}$$

The resistance for the locomotive and cars is

$$R = \frac{(9.17 \times 200) + (12.55 \times 500)}{700}$$

$$= 11.58 \text{ lb per ton}$$

The horsepower output at the wheels for balanced speed on level tangent track is

$$\frac{11.58 \times 700 \times 90}{375} = 1945 \text{ hp}$$

Adverse Design. The resistance of the locomotive is

$$R = 1.30 + 1.16 + 2.70 + \frac{(0.023 \times 4.3 + 0.0243)8100}{200}$$

$$= 10.16 \text{ lb per ton}$$

For the cars

$$R = 1.30 + 2.32 + 2.70 + \frac{(0.0694 \times 5.54 + 0.015)8100}{500}$$

$$= 12.79 \text{ lb per ton}$$

For the locomotive and cars

$$R = \frac{(10.16 \times 200) + (12.79 \times 500)}{700}$$

$$= 12.05 \text{ lb per ton}$$

The horsepower is

$$\frac{12.05 \times 700 \times 90}{375} = 2024 \text{ hp}$$

Example—Case No. 2

The conditions for this case are the same as for case No. 1, except with standard vestibuled 70-ft cars.

Ideal Design. For the locomotive

$$R = 1.30 + \frac{29}{w} + 0.03\, V + \frac{(0.023\, \sqrt[3]{L_L} + K)V^2}{W}$$

$$= 1.30 + 1.16 + 2.70 + \frac{(0.023 \times 4.3 \times 8100)}{200}$$

$$= 9.17 \text{ lb per ton}$$

For the cars

$$R = 1.30 + \frac{29}{w} + 0.03\, V + \frac{\left[0.124 \times \left(\frac{L_c}{100}\right)^{0.7} + K \right] V^2}{W}$$

$$= 1.30 + 2.32 + 2.70 + \frac{(0.124 \times 3.904 \times 8100)}{500}$$

$$= 14.17 \text{ lb per ton}$$

For the locomotive and cars

$$R = \frac{(9.17 \times 200) + (14.17 \times 500)}{700}$$

$$= 12.73 \text{ lb per ton}$$

The horsepower output at wheels for balanced speed on level tangent track is

$$\frac{12.73 \times 700 \times 90}{375} = 2140 \text{ hp}$$

Adverse Design. For the locomotive

$$R = 1.30 + 1.16 + 2.70 + \frac{(0.023 \times 4.3 + 0.0243)8100}{200}$$

$$= 10.16 \text{ lb per ton}$$

For the cars

$$R = 1.30 + 2.32 + 2.70 + \frac{(0.124 \times 3.904)8100}{500}$$

$$= 14.17 \text{ lb per ton}$$

For the locomotive and cars

$$R = \frac{(10.16 \times 200) + (14.17 \times 500)}{700}$$

$$= 13.02 \text{ lb per ton}$$

The horsepower output is

$$\frac{13.02 \times 700 \times 90}{375} = 2187 \text{ hp}$$

Example—Case No. 3

Consider a power unit articulated with a three-car (eight axles) 120-ton train 198 ft long. Assume a speed of 90 mph.

Ideal Design. The train resistance is

$$R = 1.30 + \frac{29}{w} + 0.03\,V + \frac{\left[0.07 \times \left(\frac{L}{100}\right)^{0.8} + K\right] V^2}{W}$$

$$= 1.30 + 1.94 + 2.70 + \frac{(0.07 \times 1.727 \times 8100)}{120}$$

$$= 14.10 \text{ lb per ton}$$

Horsepower output at wheels for balanced speed on level tangent track is

$$\frac{14.10 \times 120 \times 90}{375} = 406 \text{ hp}$$

Adverse Design. The train resistance is

$$R = 1.30 + 1.94 + 2.70 + \frac{(0.07 \times 1.727 + 0.015)8100}{120}$$

$$= 15.12 \text{ lb per ton}$$

The horsepower output is

$$\frac{15.12 \times 120 \times 90}{375} = 435 \text{ hp}$$

Natural or Ground Winds

The foregoing analysis of train resistance is based upon a still air condition, with the third factor of the equation [R_3] derived from wind-tunnel tests where the flow of air is parallel to the position of the train. This in effect is symbolical of actual operation, where the relative pressures and consequently the resistance elements are created only by the movement of the train itself.

It has been more or less customary in the past when considering wind conditions to assume that the maximum retarding elements were occasioned by a direct head wind and that the force of such wind should be added to the train speed, expressed in the same units, for the determination of resultant values. For example, a train speed of 60 mph and an adverse wind of 20 mph would affect the third value of the equation as follows:

No wind.................................$60^2 = 3600$
20 mph head wind.........................$(60 + 20)^2 = 6400$

which represents 6400/3600, or 1.77 times the normal drag.

DeBell[7] has given test results which indicate the effect of aerodynamic forces brought about by extraneous wind currents, and has established the value thereof at different directional angles by placing the test model obliquely to the air stream. It was thus ascertained that the maximum adverse condition was obtained when the counterbalancing air pressure was in the forward quartering position, at an angle of between 40 deg and 50 deg to the direction of movement. These ground-wind currents apparently exercise an adverse effect from zero angle, representing a direct head wind, to an angle of 120 deg or more. An advantage is reflected from this point to a direct tail wind. As expressed in a relationship to the square of the combined train speed and head wind, the increase in resistance value of the 40 deg to 50 deg forward quartering wind is of the order of 1.25 when the wind velocity is equivalent to one third of the train speed and 1.50 when the wind velocity equals the train speed.

The foregoing remarks under this subject are of more or less academic interest, because from a practical standpoint the wind varies from all directions and at different intensities, although for any given trip it is necessary to reckon upon some character of adversity which can be estimated as the square of the total, that is (train speed + wind velocity)^2. For extreme accuracy, weather-bureau records can be obtained for the territory considered. As this paper is concerned more with the application of figures for general use, it is believed that the equivalent of a direct head wind of 10 mph should be taken as a practical value for schedule calculations.

Quartering, or direct side winds, also affect flange friction R_2 and possibly, to a minor extent, journal friction R_1 due to pressure on end thrust bearings. These elements have not been considered in this analysis, due to lack of information on the subject.

Track Curve Resistance

The unit of track curve resistance appears to be uniformly established at 0.8 lb per ton per deg. This must be considered in train-resistance calculations. The alignment of the road in question must be studied, the radius of each curve multiplied by its length and the total of the resultants divided by the total length, including tangent track, of the particular section being analyzed. The average degree of curvature and the corresponding unit train resistance will be thus obtained.

Air Conditioning and Lighting

The introduction of air conditioning on railroad cars, produces a power requirement element of considerable proportions which in many cases must be converted into train-resistance units if the available total output at the motive-power wheels is used as a basis for train-operating characteristics. A lesser value must be added for lighting energy. In order to obtain proper results, the average of the maximum requirements for mechanical or electromechanical air-conditioning equipment may be taken as 25 hp per car, and the requirements for electric lights and battery charging may be taken as 5 hp per car, or a total of 30 hp per car, at speeds of 30 mph and higher. This power input to axle generators can be reduced to train-resistance values according to the following example for a 50-ton car:

$$\text{At 30 mph } \frac{\text{hp} \times 375}{S \times W} = \frac{30 \times 375}{30 \times 50} = 7.5 \text{ lb per ton}$$

$$\text{At 90 mph } \frac{\text{hp} \times 375}{S \times W} = \frac{30 \times 375}{90 \times 50} = 2.5 \text{ lb per ton}$$

At the slower speed, the power for air conditioning and lighting will exceed that required on level track for the remaining features of train operation.

The foregoing applies in part to steam air-conditioned cars. In this case, where steam motive power is used, the required amount of steam (250 lb per car) will cause a decrease in the boiler capacity available for traction and consequently reduce the wheel output, as expressed in tractive effort at a given speed, if the boiler and not the cylinders is limiting. Some additional axle-generator output is also required to operate certain air-conditioning auxiliaries, but not as much as that necessary for mechanical or electromechanical equipments.

For the streamlined articulated trains, with power units, it is the practice to supply air conditioning and lighting through the medium of an auxiliary generator driven from the main engine unit, or from an auxiliary engine set. In these cases the required power does not represent a deduction from that considered as available for traction purposes, hence the train-resistance units are not affected.

[7] "Effect of Natural Winds on Air Drag," by G. W. DeBell, *Railway Mechanical Engineer*, vol. 110, April, 1936, pp. 145–147.

Following are some examples of specific cases to show anticipated resistance units, lacking grade increments that depend entirely on profile conditions; but with assumed head wind, air-conditioning, lights, and curve-resistance units added. The streamline design and factors affecting wind resistance are assumed as having been worked out to the best advantage.

Example No. 1

Consider a streamlined 200-ton locomotive 80 ft long hauling a ten-car train, the cars of which are streamlined, weigh 50 tons each, are 70 ft long, and have an effective perimeter of 40 ft. The cars are equipped with electromechanical air-conditioning equipment and electric generators, the power requirements of which are 25 hp and 5 hp per car, respectively. Assume a head-wind velocity of 10 mph, a train speed of 90 mph, and an average track curvature of 30 min.

The resistance of the locomotive is

$$R = 1.30 + \frac{29}{w} + 0.03\,V + \frac{(0.023\sqrt[3]{L_L})V^2}{W}$$

$$= 1.30 + 1.16 + 2.70 + 4.95$$

$$= 10.11 \text{ lb per ton}$$

For the cars

$$R = 1.30 + \frac{29}{w} + 0.03\,V + \frac{\left(0.0694 \times \left(\frac{L_c}{100}\right)^{0.88}\right)V^2}{W}$$

$$= 1.30 + 2.32 + 2.70 + 7.69$$

$$= 14.01 \text{ lb per ton}$$

For air conditioning and lights

$$R = \frac{30 \times 375}{90 \times 50} = 2.50 \text{ lb per ton}$$

Therefore, the total resistance for the cars is 2.50 + 14.01 = 16.51 lb per ton. For the locomotive and cars

$$R = \frac{(10.11 \times 200) + (16.51 \times 500) + (0.4 \times 700)}{700}$$

$$= 15.09 \text{ lb per ton}$$

The horsepower output at wheels for balanced speed on level track is

$$\frac{15.09 \times 700 \times 90}{375} = 2534 \text{ hp}$$

Example No. 2

Consider a locomotive-hauled train the locomotive of which is the same as that used in example No. 1 and the cars of which are not streamlined (standard) but have the same proportions, weights, and air-conditioning and lighting equipment as the cars in example No. 1. Assume also the same head-wind velocity of 10 mph, same speed of 90 mph, and same average track curvature of 30 min as used in example No. 1. Then the resistance offered by the locomotive is 10.11 lb per ton, as calculated in example No. 1. However, for the cars

$$R = 1.30 + \frac{29}{w} + 0.03\,V + \frac{\left[0.124 \times \left(\frac{L_c}{100}\right)^{0.7}\right]V^2}{W}$$

$$= 1.30 + 2.32 + 2.70 + 9.69$$

$$= 16.01 \text{ lb per ton}$$

For air conditioning and lights

$$R = \frac{30 \times 375}{90 \times 50} = 2.50 \text{ lb per ton}$$

Therefore, the total resistance of the cars is 2.50 + 16.01 = 18.51 lb per ton. For the locomotives and cars

$$R = \frac{(10.11 \times 200) + (18.51 \times 500) + (0.4 \times 700)}{700}$$

$$= 16.51 \text{ lb per ton}$$

The horsepower output at wheels for balanced speed on level track is

$$\frac{16.51 \times 700 \times 90}{375} = 2774 \text{ hp}$$

Example No. 3

Consider a streamlined articulated eight-axle 198-ft train weighing 120 tons. Assume the head-wind velocity to be 10 mph, the train speed to be 90 mph, and the average track cruvature to be 30 min. The train resistance

$$R = 1.30 + \frac{29}{w} + 0.03\,V + \frac{\left[0.07 \times \left(\frac{L}{100}\right)^{0.8}\right]V^2}{W}$$

$$= 1.30 + 1.94 + 2.70 + 10.07 = 16.01 \text{ lb per ton}$$

The total resistance including track curvature is

$$\frac{(16.01 \times 120) + (0.4 \times 120)}{120} = 16.41 \text{ lb per ton}$$

The horsepower output at wheels for balanced speed on level track is

$$\frac{16.41 \times 120 \times 90}{375} = 473 \text{ hp}$$

Conclusion

It has been the purpose of this article to set forth all of the factors affecting train resistance, which apply in general to modern railroad passenger-train operation. If analyzed in a critical manner for a particular set of conditions, undoubtedly minor adjustments will be in order since resistance units will be affected by details in the shapes of such details as the head end, tail end, roof, wheel fairings, and window embrasures. It is believed, however, that for ordinary use the formulas herein given, and the remarks applicable thereto, will be of service.

Sanforizing Methods Up to Date

By C. H. RAMSEY,[1] PATERSON, N. J.

After commenting briefly on the increase in the production of sanforized shrunk goods of over 824 per cent in five years, which he states is one of the most startling extensions of a new process in the history of the textile industry, the author describes the types of machine that were used in 1930 when the process was more or less of an experiment. The process is next outlined, and the different types of machine that are now commercially available are described. One of these finishes fabric on one side only, while the other turns out cloth that is accurately shrunk in both warp and weft to its potential wash shrink and has an acceptable finish on both sides. The mechanical means provided to secure the proper relation of the different units of the machine and the prevention of scorching of either the cloth or the fabric are described.

ONLY SIX years ago, sanforizing was considered as an experiment. The three units of equipment then in operation processed only 364,000 yd of cloth. Five years later, the 80 machines installed in 51 plants processed 300,000,000 yd, and, by 1935, the production of sanforized shrunk goods had increased over 824 per cent, as compared with the volume of five years earlier.

The process and machinery used commercially were described in a paper that was presented at the 1931 Annual Meeting of The American Society of Mechanical Engineers.[2] The side of the early machines was left open, thus ignoring the safety factor, leaving moving parts unprotected, and allowing wasteful radiation of heat from cylinder heads and side walls. The small drying cylinder of this machine was at the top, and its effective envelopment by the blanket without recourse to additional guide rolls, which is undesirable, was impossible. This construction prevented ready access to the drying cylinder, required excessive headroom, increased the difficulty of changing the blanket, and precluded the full skying of blanket and processed fabric over the rising heat of both cylinders.

In these machines, the cloth is laid on the blanket at the beginning or point of greatest expansion, and pressure of the electrically heated ironing shoes causes it to adhere. As can be seen from Fig. 1, the shoe is shaped to hold the cloth against the expanded element until it makes contact with the drying cylinder that moves down to receive it. The surface of the blanket, contracting as its curvature is reversed, shrinks the web adhering to it in direct proportion. This shrink will always be the same for any given thickness of blanket and will exceed that necessary to meet the potential wash-shrink dimension. However, the surface speed of the drying cylinder is proportioned, through adjustable

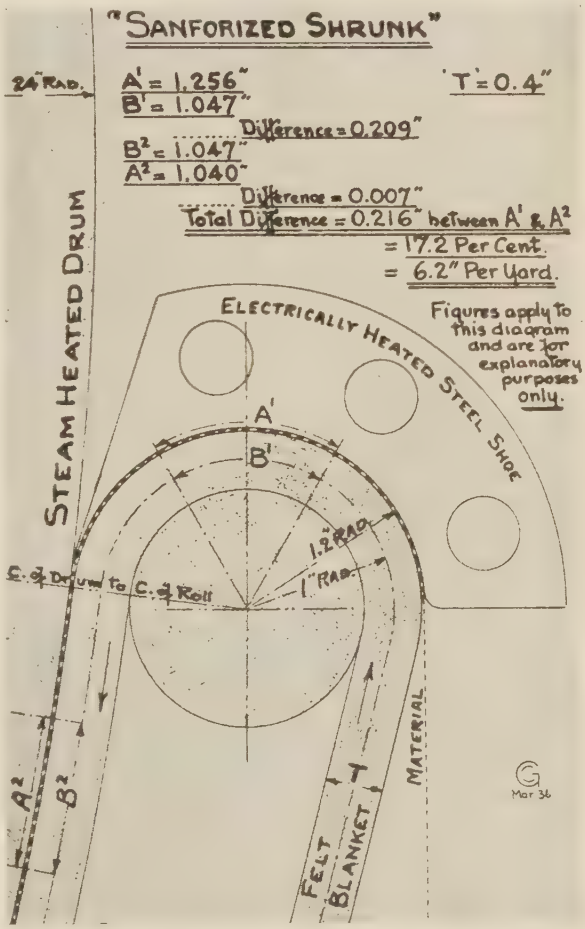

Fig. 1 Modified Palmer of the Sanforizing Apparatus Which Shrinks the Fabric to Length

gear connections, to the shrink required and will pull the fabric sufficiently by warpwise tension to correct this overshrink.

Enclosing Sides of Machine Increases Production

In a more recent sanforizing modified palmer unit, which is shown in Fig. 2, the drying cylinder has been lowered and a highly desirable streamline effect has been secured. This arrangement provides the maximum skying of both blanket and fabric over the rising heat from both cylinders, which is further induced by enclosing the sides of the machine and thus increasing production. Obviously, the enclosure is also highly conducive to the

[1] President, Morrison Machine Co. Mem. A.S.M.E. Mr. Ramsey's connection with the metal-working industry dates back to 1896 when he was employed by John Royle & Sons, Paterson, N. J., as a machinist's apprentice. In the 17 years that he was associated with this firm, he was, successively, journeyman machinist, draftsman, machine designer, and superintendent. He secured his mechanical and engineering education by supplementing his practical experience with reading and study, correspondence-school courses, private tutors, and special instruction in machine design. Immediately after leaving John Royle & Sons, Mr. Ramsey purchased an interest in the Morrison Machine Co., also of Paterson, builder of textile and power-transmission machinery. He became president of the company shortly after becoming associated with it and has held this position for more than 20 years.

[2] "Sanforizing Process," by Sanford L. Cluett, Trans. A.S.M.E., vol. 55, 1933, paper TEX-55-2.

Contributed by the Textile Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., Nov. 30 to Dec. 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until July 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Fig. 2 A More Recent Development Showing the Ironing-Shoe Assembly

safety and comfort of the operator, cleanliness of the fabric, and protection to the moving parts of the machine.

During the shrinking process, the cloth passes from left to right. The first unit, which is called the holdback or feeding machine, consists essentially of a pair of draw rolls before which tension devices and cloth guiders are mounted. This and each modified palmer unit are equipped with quick-change gearboxes to keep them in the proper relation to each other for the shrink required by the fabric being processed. The gearbox on the feeding machine has seven change gears controlling the shrink in increments of 1 in. per yd, while that on the modified palmer has three shrink gears giving increments of $^1/_4$ in. per yd. Thus, any shrink from 0 to $7^3/_4$ in. per yd which the blanket is capable of producing is readily obtainable. In addition, gears securing actual stretch of the fabric, as well as synchronism of the units, are also provided.

Attached to the feeding machine is a set of atomizer heads for spraying a fine mist of water on either or both sides of the fabric as may be required. Thence, the cloth passes over a system of steaming pipes, which, together with the atomizers, render the cloth plastic and susceptible to the changes about to take place.

On the entering end of the modified palmer unit, an adjustable-type spreading device causes the introduction of the cloth to the flexed shrinking element in proper width and free from wrinkles or scrimps. Between the feeding machine and the spreading device, the cloth, in a plastic condition, is held under enough warpwise tension to crinkle the weft threads sufficiently to meet or slightly exceed the previously determined wash-shrink potential dimension, and the spreading device brings the cloth to the exact width required and delivers it to the warp shrinking element without further change. This spreader arrangement is still useful for handling fabrics belonging to the denim family but has been superseded by a more accurate device for other cloths where greater uniformity is required.

Blankets of various thicknesses are used to secure definite shrink requirements. As all blankets are subject to wear and reduction of thickness in use, a series of feed rolls with diametral increments of $^1/_{32}$ in. is provided to maintain complete contact between the shoe and the cloth, the resilience of the blanket rendering more minute increments unnecessary. The woolen belt or blanket is endless and is provided with means for confining the sidewise creep within the limits of the cylinders over which it rides. Once, this was manually controlled but is now accomplished automatically by a motor-driven guide roll that is actuated by a mercury switch provided with suitable detector fingers. This guide roll holds the blanket near the center of the cylinder periphery, allowing only a very small lateral movement.

The electrically heated shoes are thermostatically controlled with a 15-F differential and remain in contact with the cloth or the blanket only while the machine is in motion. If, for any reason, the machine stops, the shoes automatically rise from the operating position after it comes to a full stop, thus precluding the possibility of scorching either fabric or blanket. This is accomplished by a governor-type circuit breaker that lifts the shoes by gravity-actuated balance weights, and, as the shoes rise, the current is automatically shut off. Coincidentally with the machine starting, the current is switched on as the shoes return to the operating position where they are held by a solenoid valve-controlled air cylinder.

The processed fabric leaves the cylinder and blanket accurately shrunk in both warp and weft to its potential wash shrink and permanently set in this condition. In addition, the shrinking process has improved the finished appearance of the fabric, the full crinkle of the fibers catching and reflecting the light. Finally, the processed cloth is lightly plaited down into waiting trucks ready to be folded and packaged for shipment.

Duplex Machine Developed to Finish Both Sides of Fabric

As the processed fabric leaves the machine, one side has an entirely different surface from the other. On several fabrics, this is perfectly satisfactory, but, on many others, this is definitely objectionable, and the duplex machine was developed to meet this condition. A battery of these machines, as viewed from the

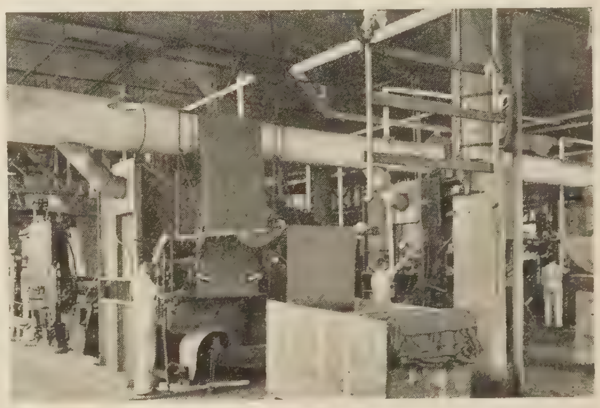

Fig. 3 Entering End of a Battery of Duplex Machines

entering end, is illustrated in Fig. 3. An additional modified palmer of smaller size, sometimes called a reverse finisher, has been added. The cloth passes over an atomizer, which is located between the two modified palmers and slightly moistens the side of the fabric that was against the blanket of the first machine. This moistening usually is not sufficient to penetrate the fabric. The cloth then passes up and around the heating cylinder of the second modified palmer unit with the moistened face of the cloth against the heating cylinder, and an equally acceptable finish on both sides is secured.

Fig. 4 is a close-up of the clip expander, which precedes the main modified palmer unit in the duplex machine. This resembles a miniature tenter and has small automatic clips that grip the edges of the fabric and keep the width uniform and accurate within the limits of the cloth being processed. The machine is connected to the power source by a telescopic shaft and can be moved back and forth over the track on which it rides on flanged wheels without disconnection. Stops are provided on both ends of the track to prevent overtravel and can be adjusted to set the expander in the correct relation to the shrinking element. Motion back and forth on the tracks is easily secured by a handwheel and also provides ready access to the shoes and shoe area to facilitate adjustment and replacement of shoes, feed rolls, and blanket. Vertical adjustment is also important; hence, the frame is hinged at the entering end, and the delivery end can be raised or lowered as required. The expander can be locked in either the operating or nonoperating position by a clamping bracket which also acts as a support for the telescopic-shaft envelope.

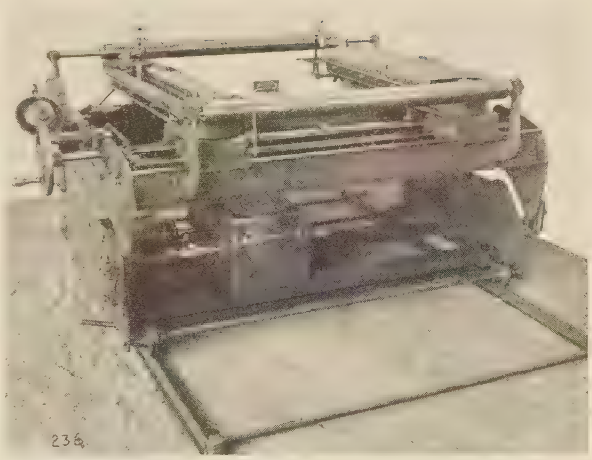

Fig. 4 Another View of the Same Battery, Showing the Clip Expander at Work

The most modern type of simplex sanforizer is fitted with a main cylinder that is 84 in. in diameter, a clip expander, and a new skying device in the steaming chamber. This device consists of a bronze frame supporting 11 brass rollers that are mounted on brass shafts with stainless-steel ball bearings. With it, the cloth remains in the moistening area much longer, which materially increases the plasticity. A unit of this type is shown in Fig. 5.

Discussion

New Spring Formulas and New Materials for Precision Spring Scales[1]

R. F. Vogt.[2] The authors have analyzed very admirably the helical-spring problem, and contributed thereby much to the general knowledge of the characteristics of helical springs. It may be of interest to know, however, that the authors' Equation [38] may be changed advantageously into a more convenient form by substituting f for $H - H_0$, where f designates the spring deflection due to the load P. Making this substitution in the authors' Equation [38] and rearranging, the equation becomes

$$f^2 \frac{PR_0^2}{3GJL}\left(3 - \frac{2GJ}{EI}\right) + f\left[1 + \frac{PR_0^2H_0}{GJL}\left(3 - \frac{2GJ}{EI}\right)\right] + \frac{PR_0^2H_0^2}{GJL}\left(1 - \frac{GJ}{EI}\right) - \frac{PR_0^2L}{GJ} - \frac{KLP}{2AG} = 0$$

which may be simplified into

$$f^2 \frac{1}{3L}\left(3 - \frac{2GJ}{EI}\right) + f\left[\frac{GJ}{PR_0^2} + \frac{H_0}{L}\left(3 - \frac{2GJ}{EI}\right)\right] + \frac{H_0^2}{L}\left(1 - \frac{GJ}{EI}\right) - L - \frac{KLd^2}{16 R_0^2} = 0$$

or

$$af^2 + bf + c = 0$$

from which

$$f = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

In these equations H_0 is the height of the helix when the load $P = 0$, which load P is positive when the load extends the spring, and negative when it compresses the spring.

Due to the curvature effect of the spring bar, the deflection for pure-shear load is only one half of the amount provided by the authors; the explanation for this characteristic is given by Röver.[3]

After it was shown by the authors that the deflection curve of the helical spring is not a straight line, as indicated by the conventional spring formula, it likely will interest some readers to know the amount of inaccuracy involved by the use of the conventional spring formula. For this purpose the writer determined the deflection resulting by the use of the various formulas for a spring of the following specifications: $d = 1$ in., $L = 100$ in., $G = 11{,}700{,}000$ lb per sq in., and $G/E = 0.392$. For the tension spring $H_0 = 5.3$ in., and for the compression spring $H_0 = 8.5$ in. The deflections for $P = 4000$ lb are: $f_1 = 3.13413$, $f_2 = 3.160248$, $f_3 = 3.1659218$, and $f_4 = 3.1493715$.

The first value f_1 is derived from the conventional formula $f_1 = PR_0^2L/GJ$ in which $\cos^2 \phi$, bending, direct-shear deflections, and influence of change in radius R and wire length L are neglected. The second value, $f_2 = (PR_0^2L/GJ)[1 + 0.3\,(d^2 2/R_0)^2]$, as proposed by the writer[4,5] adds to f_1 the direct-shear deflection. The third and fourth values $f_{3,4} = \dfrac{-b \pm \sqrt{b^2 - 4ac}}{2a}$, as developed from authors' calculations, include in addition the bending deflection, the influence of $\cos^2 \phi$, and the change in R_1; f_3 referring to the compression spring and f_4 to the tension spring.

As may be expected, due to the slight change of the coil radius R, the deflection for the compression spring is larger than for the tension spring for the same load and same dimensions of spring, as shown in the foregoing example. The writer's formula for f_2 gives a value which lies between those for the compression and tension springs, while the conventional formulas give a value which is slightly less. These values represent the deflection for a spring loaded to its maximum capacity. The differences, therefore, are maximums. This would indicate that the writer's formula has a maximum error of approximately —0.18 per cent in case of a compression spring, while for the tension spring the error amounts to +0.35 per cent. These percentages decrease in proportion to the load. The conventional spring equation produces an error of —1 per cent for a compression spring, and —0.47 per cent for a tension spring.

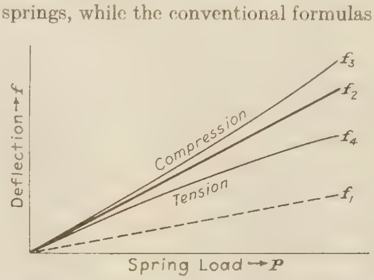

Fig. 1 Deflection Curves

The deflection results for various loads for the example mentioned show that the percentage of error in f_2 in reference to f_3 and f_4 is proportional to the load, or

$$\frac{(f_3' - f_2')/f_3'}{(f_3'' - f_2'')/f_3''} = \frac{P'}{P''} \qquad \frac{(f_4' - f_2')/f_4'}{(f_4'' - f_2'')/f_4''} = \frac{P'}{P''}$$

The deflection curves for f_1, f_2, f_3, and f_4 are shown in Fig. 1 of this discussion, in which the curves of f_2, f_4, and f_1 are exaggerated for demonstration purposes.

R. W. Carson.[6] In connection with an investigation now being conducted to determine the hysteresis or elastic lag in various spring materials, specimens of the "Iso-Elastic" material, mentioned by the authors, were obtained from John Chatillon & Sons. The elastic lag was measured as the slow change in deflection when test pieces were subjected to a steady bending load, the changes being recorded on a chart.

Since these elastic-lag effects are small, highly sensitive measurements are necessary. Mr. Sayre[7] has obtained sensitivity

by using very long gage lengths. The method described by the writer in this discussion is based on sensitive linear measurements of beam deflections, using small specimens that can be readily heat-treated and handled without introducing internal stresses.

Specimens for these tests were rolled from cold-drawn wire of about $^1/_{16}$ in. in diameter to a rectangular cross section of 0.017 in. thick and 0.156 in. wide, and heat-treated at 650 F for 20 min. Strips about 4 in. long were cut from this material and loaded as cantilever beams, measuring deflections with an electronic micrometer sensitive to displacements of less than 0.00001 in.

The measuring instrument uses electronic means for indicating point of contact between a micrometer and the specimen. This principle was incorporated in a measuring device previously described by the writer,[8] but the use of a new type of relay, recently developed by the Westinghouse Electric & Manufacturing Company, has resulted in increased sensitivity and reliability needed to measure the small elastic lag in the Iso-Elastic material.

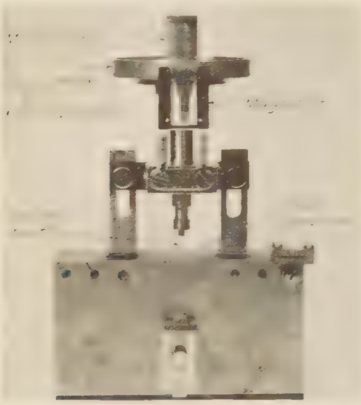

Fig. 2 Electronic Micrometer

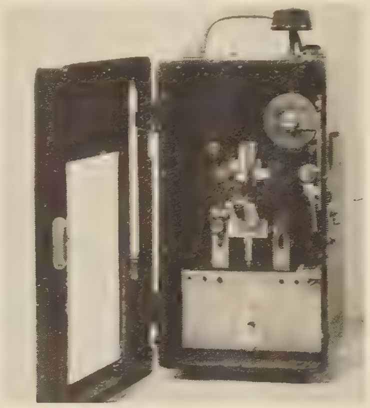

Fig. 3 Electronic Micrometer With Drive Used to Set It to Exact Point of Contact on the Specimen

With the redesigned equipment, permanent records of ribbon deflections are made on a paper chart that can be read to 0.000002 in. With this increased sensitivity, reliable and accurate measurements of elastic lag are made on relatively small test specimens under deflections producing maximum fiber stresses as low as 10,000 lb per sq in., even with specimens having low inherent hysteresis.

The measuring unit, shown in Fig. 2 of this discussion, consists of a block of brass on which the micrometer is supported on an insulating bracket. The end of the micrometer is fitted with a needle point which is brought into contact with the specimen by screwing down the micrometer. A large-diameter barrel on the micrometer, viewed through a magnifier lens assists in reading the micrometer, while a constant tension thread drive through a gear reduction, shown in Fig. 3 of this discussion, aids in setting the micrometer to the exact point of contact.

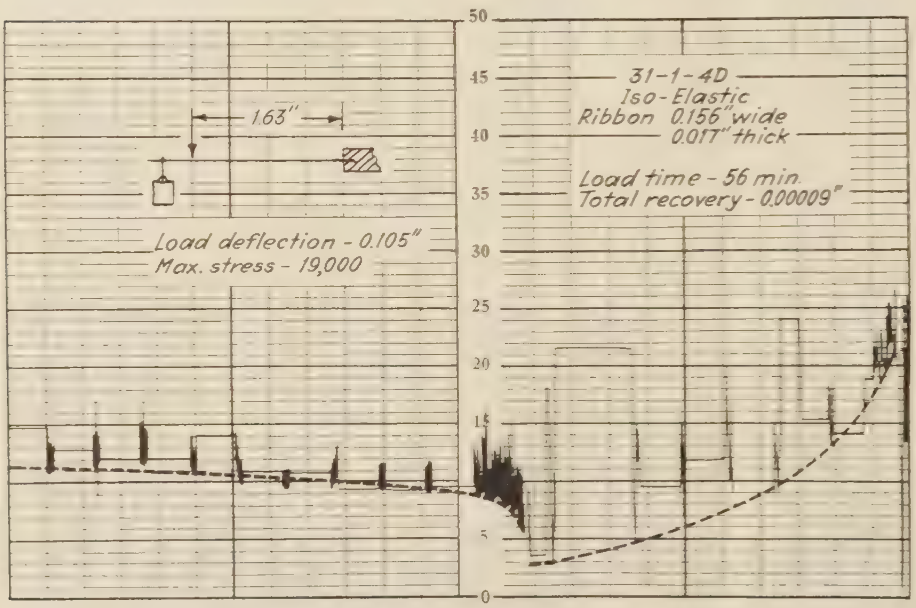

Fig. 4 Record Made by the Electronic Micrometer
(Test starts at right.)

Records are made by the instrument on a continuous-roll chart advancing 4 in. per hr. The chart, which is $5^1/_2$ in. wide, carries 10 main divisions, each with five small divisions. The recorder is designed so that each small division is 0.00001 in., while full scale is 0.0005 in. In the portion of the chart shown here, the test starts at the right, and only a part of the recovery curve is reproduced.

In conducting a test, specimens are clamped in the micrometer support, and allowed to rest several hours until a stable condition is obtained. The ribbons are then stressed for 1 hr by hanging a weight on the ribbon, and the recovery measured after removing the weight.

The instrument automatically makes a group of records of ribbon position during about 1 min in each period of 6 min. These automatic records are obtained by the use of a small electric motor in the recorder which screws the micrometer down until contact is made. This contact through the electronic relay reverses the motor, withdrawing the micrometer from contact, and the operation is then repeated.

In a typical record, shown in Fig. 4 of this discussion, the recorded points indicating ribbon position are connected by a smooth curve. To show more accurately the rapid changes in ribbon deflection occurring immediately after removal of load, the recorder is operated continuously for several minutes.

From these records, the total recovery is measured, and the ratio of total recovery to load deflection determined. For stable conditions obtained after two or three preliminary tests, the creep recovery or elastic lag for the Iso-Elastic specimens used in these tests is from 0.04 to 0.06 per cent of the load deflection.

Disregarding the effects measured during the first minute after removing the load, the recovery follows a logarithmic curve to final recovery, as shown in Fig. 5 of this discussion, with final recovery occurring in about 10 to 12 hr under the load conditions given on the curve. Conditions during the first minute seem to follow a different routine. For perhaps 20 sec after unloading nothing much happens. Then the spring rapidly recovers about one third of the creep during the first 5 min. The remainder of the creep follows an averaged logarithmic curve.

The irregularities shown in the recovery portion in Fig. 4 of this discussion are characteristic. These irregularities are of the order of 10 times the sensitivity of the device, and are not instrument errors, nor are they produced by vibration of the specimen. All attempts to eliminate these irregularities have failed. At present the variations are averaged in plotting the data.

New Laboratory Data Relative to Embrittlement in Steam Boilers[1]

E. P. Partridge.[2] The information presented by the authors, and by W. C. Schroeder and A. A. Berk in another paper,[3] relative to the fundamental part played by silica in promoting embrittlement of boiler steel exceeds in importance anything that has been presented on the subject since the inception of the work at the University of Illinois.[4] In Progress Reports Nos. 4 and 6 of the Joint Research Committee on Boiler Feedwater Studies,[5,6,7] it seemed that the extensive data in those reports[5,6] were thoroughly in contradiction with the earlier results given by F. G. Straub,[4] as were also the conclusions of several other investigators, both in this country and abroad. With the discovery of the effect of silica, all of the apparently discordant results can now be explained.

The writer would like to point out at this time that in spite of the 30 years of work on embrittlement, the important effect of silica would have remained unknown if an independent investigation such as the one developed under the cooperative agreement between the Joint Research Committee for Boiler Feedwater Studies[7] and the U. S. Bureau of Mines had not revealed the extent of our ignorance of the fundamental chemical factors in embrittlement. That we now have a clearer view of the subject is due to the the combined efforts of F. G. Straub,[8] W. C. Schroeder,[9] and J. H. Walker.[10] Under the direction of Mr. Walker, every effort was made during 1934 to discover the cause of the discrepancies between the results obtained at the University of Illinois[4] and those obtained at the Nonmetallic Minerals Experiment Station of U. S. Bureau of Mines maintained at Rutgers University, New Brunswick, N. J. Arrangements were made for the exchange of samples of steel, chemicals, and, if it seemed desirable, of test equipment.

The writer would like to emphasize the fact that although he was associated with the investigation conducted at New Brunswick, N. J., from its inception until September 1, 1935, the credit for discovering the action of silica in producing embrittlement belongs only to Dr. Schroeder[9] and A. A. Berk,[11] because the writer left the Bureau of Mines just prior to the work conducted with the sample of commercial caustic supplied by F. G. Straub. From the larger number of specific data given by Dr. Schroeder[3] and the confirmatory information in the authors' paper,[1] it seems safe to conclude that the widely divergent statements in the past concerning embrittlement by caustic soda are now converging to give sounder basis for the further investigations which must be made. Now that we know more accurately how embrittlement is caused, we may be able to develop more intelligently the means for its prevention.

Plunger Lift for Pumping Deep Wells[1]

C. M. Rader.[2] The writer believes that the equipment described by the authors is more important than it is generally considered to be. This is particularly true in fields depleted by gas drives rather than by water or other drives that tend to sustain a

[1] Published as paper PME-58-1, by H. W. Fletcher, in the July, 1936, issue of the A.S.M.E. Transactions.

[2] Assistant Division Superintendent, Phillips Petroleum Company, Oklahoma City, Okla.

relatively high bottom hole pressure which results in the retaining of sufficient energy within the oil body for the moving of the oil from the sand to the well bore.

In Oklahoma, as a rule, fields producing from the Wilcox horizon nearly always fall in the class of gas-drive fields. This is particularly true of the Oklahoma City field, to which field the writer's experience with the Hughes plunger lift has been limited. The same holds true, however, for the Seminole field.

Here, for various reasons including proration, large investments were made at an early date in rather elaborate high-pressure gas systems for purposes of production after natural flow had ceased.

Naturally, once such an investment was made, it had to be utilized to the utmost which meant, to the ultimate depletion of the field if possible. This view, of course, contemplated the nonpurchase of additional equipment for lifting purposes, other than that which used high-pressure gas as a lifting medium. In other words, this view called for the discarding of sucker rod pumping, or its equivalent.

Before the operators could be sold on this latter idea, they had to be assured that whatever equipment they purchased, after gas lift, would carry them through to the end of production. They saw the advantages of the straight plunger lift, as was demonstrated by their numerous purchases, and felt assured that the so-called booster pump could and would be developed in time to finish the job after straight plunger-lift operations ceased to be economical or possible.

It was felt certain that this period would come in most of the wells, for it was early demonstrated that there was no water drive. The work of Ben Lindsly, of the Bureau of Mines, demonstrated that very little gas, which, of course, is the propulsive force driving the oil through the sand to the well bore, would be available when bottom hole pressures became low. It was determined that there would eventually remain but about 1 cu ft of gas per bbl of residual oil per pound of bottom hole pressure after this pressure was reduced below 150 lb per sq in. In addition to these factors, the extreme permeability of the Wilcox sand coupled with relatively close spacing of wells pointed the way to loss of production on the part of the wells equipped with a tool that required any back pressure whatsoever on the sand face for operating purposes. Worse yet, this lost production would go to offset wells in more or less direct proportion to the amount of back pressure exerted against the face of the producing sand in the wells in question. In other words, it was anticipated by some that most of the Oklahoma City wells would eventually fall in the classification of wells 15 and 16 referred to in Table 1 of Mr. Fletcher's paper.

When making these statements, the writer must, in all fairness, refer to an article[3] wherein is a comparison of plunger-lift well production with offset well production. Offset wells were produced by beam pumping. The 1935 average for four wells operated by plunger-lifts was 1853 bbl per month, as compared to 1220 bbl per month for the several offset wells. However, several things are brought to attention by a perusal of this table:[3] First, during January, 1935, the four plunger-lift wells produced 2505 bbl as compared to the 1674 bbl of offset production; whereas, in December of the same year the plunger-lift wells produced but 1213 bbl as against 1091 bbl for the offset wells. From this it is seen that the plunger-lift wells took an average decline of 51.5 per cent during the year as compared to but 34.8 per cent for offset wells. As this decline was coincident with the period in the decline in bottom hole pressure that represented the difference between successful and relatively unsuccessful operation of the straight plunger lift, the writer believes that the beam-pumped wells will still be producing economically after the plunger-lifted wells are abandoned. Second, the wells in question are located on the west edge of the field, well down structurally, and produce from a relatively tight sand not typical of the average Wilcox sand, but more approaching the type wells listed in the upper brackets of the author's Table 1.

The writer's discussion so far has been given mostly for the benefit of those who operate in gas-drive fields only, which, as previously stated, constitute a fairly high percentage of the operations in Oklahoma, from a total production standpoint. The writer has found by experience that where other conditions are present, as outlined by Mr. Fletcher, a fairly large measure of success is assured by the plunger type of operation. There are 32 successful installations still operating in the Oklahoma City field; of this number, ten are in Wilcox-sand wells, consisting of six $2^1/_2$-in. wells, two 3-in. wells, and two 4-in. wells. The other 22 installations are operating in Simpson-sand wells. Of these 18 are in $2^1/_2$-in. wells, three are in 3-in. wells, and one is in a 4-in. well.

If the writer's information be correct, there were originally some 92 units purchased for the Oklahoma City field, 48 of which were originally installed in Wilcox-sand wells; these include 27 in $2^1/_2$-in. wells, 13 in 3-in. wells, and 8 in 4-in. wells. There were 44 installations originally made in lower Simpson-sand wells; these include 31 in $2^1/_2$-in. wells, 8 in 3-in. wells, and 5 in 4-in. wells. These purchases were begun in January, 1934.

To the best of the writer's knowledge, some 12 Simpson-sand wells and but one Wilcox-sand well have been carried to abandonment with plunger-lift equipment.

Of the 44 Simpson-sand wells originally equipped with this tool, 22 are still being produced in this manner, whereas but 9 of the 48 Wilcox-sand wells originally so equipped are being so produced.

Difficulties arising from paraffin deposition have always been of major importance in the production of oil in the Oklahoma City field. A progressive study of the operation of some 26 wells, most of which were in the Wilcox sand, indicated an average lost time due to this cause of approximately 5 or 6 per cent. This is a relatively small factor, especially when considering the fact that it normally requires the time of but one man for an hour, more or less, to get a well back on production once the stoppage occurs. Furthermore, considerable advancement has been made both in plunger design and otherwise for the combating of this trouble.

It has been noted that less paraffin trouble was experienced by 4-in. than 3-in. installations, and less by 3-in. than $2^1/_2$-in. ones. This is explained by the greater weight of the larger plungers allowing them to cut by or through paraffin bridges when falling back down the hole, and by the greater total force exerted upward by the larger plungers, for any given working pressure.

TABLE 1 RESULTS OF $2^1/_2$-IN. PLUNGER LIFT IN A TEST WELL IN THE OKLAHOMA CITY FIELD

Date	Average daily production, bbl	Average daily operation, hr	Average gas-oil ratio	Highest production, bbl per day	Minimum gas-oil ratio
October 27, 1935 November 15, 1935	130.0	19.0	4240	204	2220
December 9, 1935 January 9, 1936	90.3	20.5	2617	167	1490
January 23, 1936 February 22, 1936	119.0	20.5	2000	186	2620
March 17, 1936 March 21, 1936	99.2	19.6	2720	120	2570

Naturally, greater production is obtained by use of the larger plungers for any given working pressure, or, conversely, any given production can be obtained by use of lower pressures in the larger installations. Here, however, economics of initial investment enter, which, in conjunction with the booster-pump possi-

[3] "Producing Wells to Exhaustion by Gas-Lift," by S. F. Shaw, *Oil Weekly*, vol. 81, April 6, 1936, Table 3, p. 20.

bilities, in the majority of cases, favored the purchase of the smaller-diameter pumps.

Field experimentation with the booster pump began early in 1935, and has progressed intermittently since. It must be remembered that production depths run around 6500 ft, and allowables must be obtained if at all possible. Mistakes and false starts were inevitable where no fund of experience was available to direct the progress of the work.

Several designs for a $2^1/_2$-in. lift have been tried in a test well in the Oklahoma City field from time to time, with the results shown in Table 1 of this discussion. Down time averaged 4 hr per day, which was due largely to the freezing of input gas lines, together with a few stoppages resulting from sand and paraffin. Prior to the installation of the booster pump, this test well averaged approximately 40 bbl per day on straight plunger lift, with an input ratio of upward of 5000 cu ft per bbl.

Evan Just.[4] The writer can state that his experience in the Oklahoma City oil field corroborates the author's statements. In that field, producing from a depth of 6400 ft, 4-in. plunger lifts produce approximately 2.5 bbl per day per lb of flowing pressure, or an average of 175 bbl per day; 3-in. plunger lifts produce approximately 1.2 bbl per day per lb of flowing pressure, or an average of 109 bbl per day; and 2-in. plunger lifts produce approximately 0.6 bbl per day per lb of flowing pressure or an average of 37 bbl per day. Lifting costs, including depreciation, have been approximately one half as much as the costs of rod pumping, and the percentage of down time, which has averaged 7 per cent for plunger lifts, has been approximately one third of the down time of rod pumps. The cost of reconditioning the wells per barrel of production has been approximately one tenth the corresponding cost for rod pumping.

The principal cause of down time has been paraffin accumulation. The capacity of the plunger lift to operate in sandy wells has been comparatively remarkable.

The low reservoir pressure and high productivity index described by the author were encountered in the Wilcox zone of Oklahoma city. Where flowing pressures declined below 60 lb per sq in. the 4-in. plunger lift could not compete with the rod pumps.

Author's Closure

Mr. Rader's comments regarding the importance of the booster pump, in areas where porous strata are depleted to low end pressures, are much to the point. It is unfortunate that the necessity of maintaining allowables, and the delays in securing the necessary equipment required to make such changes as were indicated, so prolonged the experimental period that the device was not yet in commercial form at the time pressures had declined to such a value as would require its use. While the unit is necessarily more complicated than the straight plunger lift (the chief drawback being the use of a "macaroni string" laced to the working string and supported at the proper intervals for furnishing the gas supply) there has been comparatively little mechanical trouble and the operating unit has been removed and replaced in about three hours without disturbing the pipe. Work is still in progress along these lines and gives fair promise of an ultimately satisfactory conclusion.

The figures presented by Mr. Just, comparing as they do the performance of a number of units operating under commercial conditions, are interesting. The sharp reduction of down time and the even greater lowering of maintenance costs justifies the original conclusion that the use of this equipment would result in an appreciable reduction of lifting costs.

The Influence of Cutting Fluids on Tool Life in Turning Steel[1]

Arthur H. Adams.[2] This paper, which is a progress report of the Subcommittee on Cutting Fluids of the A.S.M.E. Special Research Committee on the Cutting of Metal, is an important step toward the solution of the cutting-fluid problem, and it is to be hoped that the committee will be able to continue its important work. The writer believes that some day there will be developed new and startling cutting fluids based on an unorthodox hypothesis as to their action, and he is of the opinion that this report contains justification for this belief. This moves the writer to make the criticism that the report stops blandly after the presentation of certain facts which seem to demand interpretation, and to present by the Socratic method an unorthodox hypothesis which will interpret some of the main points of the paper. These questions and answers are as follows:

Question 1: What is the main function of a cutting fluid? Answer: To lubricate the most difficult of bearings, that is, bearings between the tool and the work, and between the tool and the chip in metal-cutting operations.

Question 2: Is not the heat-removing function very important? Answer: It is probably secondary to lubrication.

Question 3: How is the answer to question 2 justified? Answer: First, by a process of reasoning that, accepting just one assumption, justifies it rigorously. Second, by the way this hypothesis, in which lubrication is the main mechanism, seems to explain otherwise uncoordinated data.

The process of reasoning mentioned in the foregoing answer is developed as follows:

Question 4: How does a tool finally fail? Answer: By becoming so dull (worn) that the thereby increased friction develops heat fast enough to overheat the tool, particularly the edge, and causes it to lose temper.

Question 5: How can a cutting fluid postpone such failure? Answer: First, it can reduce the rate at which power is used in friction by getting on the tool surfaces and doing something we will have to term "lubrication" although it is so imperfect that it bears little resemblance to ordinary lubrication. At any given stage of tool wear a slightly lessened friction, due even to most imperfect lubrication, yields a double benefit: It reduces both the next increment of wear and the heat generated. With even very imperfect lubrication it takes a duller tool to generate as much heat as without it. Second, a cutting fluid carries away heat and delays the tool in reaching temperatures that cause that loss of temper.

Question 6: Is it not tenable that, by mere carrying away of heat, a cutting fluid can reduce friction and wear?

Answer: So far as the writer knows, data are lacking on the coefficient of friction between hard tool steel and mild steel, under conditions resembling those of dry cutting tools. Therefore, it is possible that under these conditions the coefficient of friction may be found to rise with temperature; in that case cooling would reduce friction. The most nearly applicable data found are on the brakes of railroad cars. Here the coefficient of friction drops very markedly as the brake application is prolonged and as the brakes get hot. The tool frictions in metal cutting within the range below incipient temper loss have, therefore, been assumed not to rise as temperature rises. This important assumption should be checked by special test. If the assumption is seriously wrong the cooling action of the cutting fluid may be more important than the writer believes.

[1] Published as paper RP-58-11 O. W. Boston, W. W. Gilbert, and C. E. Kraus, in the July, 1936, issue of the A.S.M.E. Transactions.

[2] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

The evidence, however, of practically all speed tool-life data is not in conflict with the assumption.

Question 7: Making that assumption, what must be the effect on tool life of mere cooling?

Answer: There are two conditions to discuss: (*a*) The tool is still in such good shape and the speed is such that heat is not generated fast enough to injure the temper even if there were no cooling. While this condition lasts mere cooling is doing nothing toward postponing failure. (*b*) As soon as the tool is more worn, or if the speed be high enough so that, in the absence of cooling, the temper would be threatened, mere cooling would only then begin to postpone failure.

Let us see about how important this postponement is. Based on the previously mentioned assumption, the rate of wear is not reduced by mere cooling. Therefore, the duller the tool becomes the more power goes into wear (and heat) and the dulling of the tool is accelerated. The life of a tool cooled N deg at failure will be the same as the life of an equivalent uncooled tool of same shape and wear resistance, but of some steel able to stand a temperature N deg higher. Thus the gain by cooling is not cumulative. The gain is that the maximum dullness the tool will stand is increased a little. This is a definite tool-life gain but not a big one. Once a cooled tool is as dull as it can get and still safely run uncooled, it will not take long for it to get as dull as it can possibly run with cooling.

Question 8: If we meagerly lubricate the working area of the tool what are the gains?

Answer: Reduction in coefficient of friction. This proportionately reduces both the power lost in friction (tool wear) and the heat generated. Starting with a given tool condition, mere cooling made no reduction in the next increment of wear. Even meager lubrication makes a reduction in the next increment of wear. And another gain in the next, and the next. Cumulative gains! A slight decrease in the rate of wear for given tool conditions makes a big gain in tool life. Moreover, heat generation is reduced as much as wear; hence, tool temperature will be lower for a given condition of the tool. This fact alone yields much the same noncumulative life extension toward the end of tool life as mere cooling does.

Question 9: If lubrication is the thing, why do we not get better results when proven high-grade lubricants are tried as cutting fluids?

Answer: Because the "bearings" are so peculiar. No matter how good a cup grease you select it will not loosen rusted-in bolts. The cutting lubricant must, in all common sense, be chosen first for ability to penetrate the tool-chip bearing quickly. This bearing has no low-pressure oil entrance. The only oil grooves it has are first the cracks in the chip, which streams swiftly back over the tool, and second, the hard-packed metal particles constituting the so-called "false nose" on the tool point. No good lubricating oil could enter these oil grooves before they leave the tool. Yet that is essential.

Question 10: What properties of a cutting lubricant, then, tend to make it penetrate the tool-chip bearing quickly?

Answer: Low interfacial tension on the metal to be cut and low viscosity are both indispensable. These vary so in relative value from job to job that neither can be set first. Perhaps attention to getting the utmost in low interfacial tension (rapid wetting power) on the work (also on the tool, if not incompatible) will yield bigger dividends than trying for the utmost in low viscosity.

The properties of a good cutting lubricant, according to this hypothesis, must be varied to suit the job. This agrees with practice and explains why it has been so hard to get coordination of cutting-fluid data. If the hypothesis be true, the size and shape of the cutting tool, the depth and width of the chip, the pressure of the chip on the tool, the hardness of the metal, its toughness or brittleness, the affinity or spreading speed of the lubricant, the cutting speeds used, and many other factors all seriously affect the properties a good cutting lubricant needs. Metal that cuts short, i.e., with easily broken chips having good sized fissures, does not need a fluid of as low viscosity as more malleable metal. The higher the cutting speed the swifter must be the penetrating action of the fluid to reach the tool at all.

Question 11: If such swift penetration be required for tough metals and for high speeds, how can a liquid of the requisite fluidity be of any use when it does get near the tool point?

Answer: Anything at all on the tool at the pressure points, even water, is vastly better than a splendid high-pressure lubricant on the outside only. This is the reason why conclusion 9 of the report shows water, and borax water the best of all, for the top speeds.

The case of mineral oil before and after treating with Oildag, as presented in the paper, should be discussed. A corollary of the penetration-lubrication hypothesis, formulated many years ago by the writer, is that some day a suitable low-viscosity, high-flash-point liquid, of high wetting power for metals may be discovered and be made to carry some dispersed solid having, like colloidal graphite, an affinity for steel. By this means the swiftest penetration could be combined with the highest pressure-resisting lubrication. Such a thin fluid would not itself lubricate much, but it would be the penetrant carrier to insure constant rebuilding on the tool of a wear-resisting surface. Such a combination might be a universal cutting fluid. Years ago the writer experimented briefly with kerosene and Oildag in these rôles, with just enough success to become convinced of the correctness of the thought and of the incorrectness of kerosene in that rôle.

Professor Boston's light mineral oil with Oildag renews the writer's enthusiasm for exploration in this territory. Consider the curves M and M-20 of Fig. 10 of the paper. This oil is little better than nothing. We add 0.15 per cent of colloidal graphite and it becomes better than all other fluids tried. Quite remarkable results for so slight a change in the oil itself.

Let us see if the hypothesis can give an answer to this. This neutral oil, without fatty acid, is certainly not as vigorous a wettant for steel as the sulphurized-base oils. Very light, as oils go, it still has a viscosity of a different order from water and the aqueous fluids. It is then inferior in both of those properties found indispensable by the hypothesis. Note, however, that it is a little better than nothing. One therefore asks what effect did the addition of a trifling amount of Oildag have? It cannot be argued that the heat-removing properties were enhanced by its addition.

Let us suppose this oil, which is better than nothing, does penetrate in minute amounts. Possibly traces, clinging on the hot tool next to the chip, become fluid enough to be drawn swiftly into the chip fissures. These traces, when carrying graphite, deposit it sparsely on the tool. This brings about a new effect. It is well known that the wetting power of oil for a graphitized surface is very high. Our oil has suddenly become a vigorous wettant for the tool. This partially overcomes its handicap of having a rather too high viscosity. It gets in, at least in sufficient quantities to maintain a fair film of graphite despite the pressure, particularly at all the lower speeds. The handicap of excessive velocity is still there. The M-20 curve approaches the M curve at the higher speeds.

Suggestion is often better than elaboration. There are a hundred almost equally interesting discussions possible of the data in this one report. Do they not indicate a new field of research which will include the following items?

(*a*) Measurement of heat generated (or of power input) with different fluids, and determination of whether the better cutting

fluid does not invariably generate less heat. This should be a crucial experiment for the hypothesis.

(*b*) Viscosity-temperature data to be determined for all fluids, and wetting-power research for all on different metals.

(*c*) More exhaustive speed-tool-life studies, all interpretable by the light of the penetration-lubrication hypothesis.

(*d*) The job of modifying and refining the hypothesis and reducing to mathematical expression.

(*e*) In the end, perhaps, development of that ideal cutting fluid, or of a series of them for different metals.

Hans Ernst.[3] The tests reported in this paper are of especial interest in that they call attention indirectly to the two principal functions of a cutting fluid, namely, cooling and lubrication. These two functions are independent, and are not here named in the order of their importance; either may assume the paramount rôle under certain cutting conditions. Both are important from the standpoint of chip formation. The built-up edge which precedes the nose of the cutting tool largely determines the finish of the work and the tool wear. The magnitude of this built-up edge depends largely on the lubrication of the tool face and the structure of the metal immediately ahead of the tool; the plasticity of this material is affected by the coolant.

The independence of these functions, and their varying relative importance, is particularly emphasized by the results of the tests on colloidal graphite. In the equation $VT^n = C$, a marked reduction in the exponent n is shown with increasing additions of graphite to the soluble oil, and a still greater reduction by similar additions to the mineral-oil carrier; there is also, in each case, a small reduction in the constant C. As shown by the authors, this combination effects a counterclockwise rotation of the tool-life cutting-speed curve about a point corresponding to a relatively low tool life, thus indicating a marked increase in the tool life, for the lower cutting speeds, and a small reduction in tool life for the higher cutting speeds.

But an increase in the percentage of graphite content, and again a change from a soluble-oil carrier to a mineral-oil carrier, undoubtedly increases the lubricating value of the fluid, particularly where conditions of boundary lubrication are encountered. Thus, it appears that the lubricating function of the cutting fluid is of prime importance at the lower cutting speeds.

On the other hand, at the highest cutting speeds, this increase in lubricating value apparently causes a decrease in tool life. This seeming anomaly may perhaps be explained by the fact that, in general, an increase in the lubricating value (as by changing from the soluble-oil to the mineral-oil carrier) is accompanied by a reduction in the specific heat, with a corresponding reduction in the cooling effect. Thus, at the highest cutting speeds, the reduction in cooling effect overshadows the improvement due to better lubrication. As the authors have mentioned, the thermal conductivity or the ability of the fluid to carry off heat, is not necessarily a direct function of the specific heat.

Further evidence for this is given by the curve for the borax-water solution, that is, curve *WB* in Fig. 5 of the paper. Here the lubricating value is obviously very small, yet the constant C is higher than that of any of the other cutting fluids in this series of tests. This is probably due to its high value as a coolant.

From the foregoing it appears evident that the ideal cutting fluid is one which combines to the fullest extent high cooling effect and high lubricating value (under the conditions of temperature and pressure which exist at the nose of the cutting tool); it is for this reason that improvement is generally obtained by the use of sulphur or some other substance which gives the cutting fluid the characteristics of an extreme-pressure lubricant. As these two properties are largely opposed to each other in commercial cutting fluids, some cooling effect must usually be sacrificed at the lower cutting speeds in order to obtain the maximum lubricating value; and conversely, some lubricating value must be sacrificed at the higher cutting speeds in order to obtain the maximum cooling effect.

Raymond Szymanowitz.[4] The authors' formula for the cutting-speed tool-life relationship, $VT^n = C$, has an economic as well as a mathematical meaning. The exponent n, as was pointed out, is affected by the cutting fluid used, other conditions remaining constant. This exponent which is a mathematical symbol for the rate of change of cutting-speed with tool-life, is shown to decrease appreciably when using colloidal graphite in plain mineral oil as the cutting fluid. From an economic standpoint, this means that the manufacturers' present equipment can be speeded up to meet seasonal or emergency demands with less tool trouble.

While discussing the economic phase of the subject, the writer would like to point out that the addition of colloidal graphite to plain mineral oil yields an increase in production of 25 per cent, at an increase in cost of only 3.9 per cent. To the person who would like to make some practical use of this research report, these figures seem to be the crux of the matter. These figures have been arrived at in a manner similar to those given in the paper.

For a constant tool life of 300 min as seen from Fig. 10 of the paper, the cutting speed for the plain mineral oil is 77 fpm; for the sulphurized oil it is 86 fpm; and for the mineral oil plus colloidal graphite (*M*-2-0) it is 96 fpm. The increase in speed or production for the sulphurized oil over the plain mineral oil is approximately 12 per cent, and for the mineral oil plus colloidal graphite over the plain oil it is 25 per cent. The mineral oil plus the necessary colloidal graphite (0.153 per cent colloidal graphite by weight) costs 35 cents. Assuming, as was done in the paper, the use of these oils on an automatic screw machine in which 1 gal of cutting fluid is added per hour, we have the values given in Table 1. The prices given in this table have been selected for comparison only and are subject to revision depending on quantity purchases.

TABLE 1 COMPARATIVE COSTS OF COLLOIDAL GRAPHITE, PLAIN OIL, AND SULPHURIZED OIL WHEN USED AS CUTTING FLUIDS

	Type of Oil		
	Plain	Sulphurized	Mineral plus colloidal graphite
Direct labor cost	$0.40	$0.40	$0.40
Total cost, material and grinding	0.20	0.20	0.20
Machine overhead	4.00	4.00	4.00
Cutting-fluid cost, plain oil	0.16	0.24	0.16
Colloidal graphite	...	...	0.19
Total cost	$4.76	$4.84	$4.95
Increased cost over that of plain oil	...	$0.08	$0.19
Increased cost over that of plain oil, per cent	...	1.68	3.90
Increased production over that of plain oil, per cent	...	12.00	25.00

The authors have indicated that they obtained better results with colloidal graphite in oil than when the graphite was suspended in water. The writer, however, would like to cite a very favorable report[5] on the use of colloidal graphite in water as a cutting lubricant which appeared in 1910. In this report it is said that colloidal graphite in water used as a cooling lubricant for die cutting of pipe threads enables the same to be done with one passage of the die instead of two, which was the custom

[3] Research Engineer, Cincinnati Milling Machine Company, Cincinnati, Ohio. Mem. A.S.M.E.

[4] Technical Director, Acheson Colloids Corporation, Port Huron, Mich.

[5] "Aquadag as a Lubricant," *Chemical and Metallurgical Engineering*, vol. 8, 1910, p. 293.

when using lard oil on this particular job. Furthermore, the threads cut with the colloidal graphite in water were shown to be cleaner and sharper.

This article[5] also reports that in a lathe operation comprising the cutting off of a large number of cold-rolled steel rods of 1 in. diameter, the number of cuts the tool made with one sharpening were 60 when using ordinary soap compound, whereas when using colloidal graphite in water the same tool made 980 cuts with only a single sharpening.

This article[5] and several instances on record have shown that there are times when colloidal graphite in water does a remarkably good job in increasing quality and production.

It might be well to emphasize the fact that colloidal electric-furnace graphite is abrasive-free, inert chemically, and of a particle size that makes it, for all practical purposes, the equivalent of a substance in true solution. Being inert it does not promote corrosion, nor is it altered by those influences which affect less stable substances. It would seem that colloidal graphite possesses many possibilities in the cutting-fluid field and that a wider practical use of the same in this connection is worthy of serious consideration.

E. M. Barber.[6] The writer believes that questions relating to the application of cutting fluids can be most advantageously answered and our knowledge of cutting-fluid performance developed into a practical basis for cutting-fluid specifications that will be of general practical value only through a program involving the following two fundamental steps: (1) Discovery and at least qualitative proof of the mechanism of cutting-fluid action; and (2) correlation of the case histories of individual tests in the light of this mechanism.

If this sort of a program is not carried out our knowledge of the performance of cutting fluids must remain that of a series of unrelated case histories. Thus, for example, we may learn that some particular cutting fluid is more efficacious than any other that we have tried when it is used on some particular job, but we do not know that it will be equally good on some other job. As a matter of fact, we strongly suspect that it will not, and the authors' tests with a constant area of cut but using a thick shallow chip and a thin deep cut confirm this suspicion. Even with this slight change, the order of rating of the oils was revised.

We must learn in a more general way, first, what are the properties of a good cutting fluid that make it a good cutting fluid and, second, to what extent are these properties desirable in cutting fluids for different applications?

The Texas Company has recently instigated a program of cutting-oil research, one phase of which involves the measurement of surface finish as a function of the cutting fluid and the cutting conditions. For the time being a lead abrasive method has been selected for the measurement of surface finish.

During the progress of this research a number of experiments have been performed to investigate various ideas of the action of a cutting fluid and the mechanism by which it functions. Following are a few selected examples of these tests.

1 It was suggested that the cutting fluid influences the finish of the work by controlling the friction and the back pressures between the chip and the tool, and that this hypothesis may be tested by experiments in which the friction on the top of the tool is deliberately increased and decreased over a considerable range.

To obtain variations in the friction between the chip and the tool, the rake of the tool was ground transverse to the length of the tool with wheels of varying grit. In preparing these tools the grinding wheel was not allowed to touch the cutting edge of the tool but was used merely to change the finish on the rake surface across which the chip must slide.

It was found that the friction between the chip and the tool had a very decided effect on surface finish; the higher the friction (rougher the rake surface) the rougher the surface of the finished work. A similar result was obtained when the chip clearance was restricted so that the chip could not flow freely away from the work.

2 It was also suggested that the cutting fluid reaches its position between the chip and the tool by flowing into a tiny crack that precedes the point of the tool. Thus, in addition to its ability to provide effective lubrication under extreme conditions of pressure and temperature, the oil must be able to penetrate well enough to get into a position to do its lubrication. It is believed that the penetrating ability of the oil is merely a matter of viscous flow into the crack under the pressure caused by the vacuum that is created when the work is fractured.

Thus, a curve of surface finish versus cutting speed would be expected to show a rather sudden deterioration in surface finish when the cutting speed becomes so high that the fluid is too viscous to flow into the crack fast enough to provide effective lubrication. This has been checked by running curves of surface finish versus cutting speed with oils of different viscosities. As the result it was found that for an oil of given viscosity there is a speed (feed, speed, material, and all other factors remaining constant) above which the oil no longer provides lubrication and that this speed varies directly as the fluidity of the cutting oil.

3 Another point that seems to follow from this conception of cutting-fluid action is that, all other conditions remaining constant, any one cutting fluid will maintain its effectiveness to a higher speed the narrower the cut. This occurred by virtue of the reduced length of the crack into which the fluid must flow in order to get between the chip and the tool. Tests were run to check this point and it was found that a given cutting fluid retained its effectiveness to a higher cutting speed with the narrow cut than with the wide cut.

There are many other factors concerned with the action of cutting fluids that have been or are under investigation as a part of our program; among the most important of these are the determination of that property by virtue of which a cutting fluid provides effective lubrication between the chip and the tool, and the reasons for variations in the effectiveness of different cutting fluids when used in different cutting processes.

It is interesting to note that many of the differences in tool life reported in the paper which cannot be accounted for by ordinary differences in the coolant action are explicable in terms of the foregoing conception of cutting-fluid action.

As one who is interested in experiments of the same sort as those outlined in this paper, the writer would like to ask the following questions:

1 What is the accuracy and reproducibility of the results? That is, how great were the variations in the 10 to 15 observations that were made on each point?

2 Were tool temperature measurements made concurrently with these tests? If so, was any correlation observed between cutting temperatures and tool life?

3 How was the sudden breakdown of the tool detected?

M. E. Lange.[7] Much laboratory work has been done in the machine field which deals with phases of metal cutting that are far removed from conditions actually encountered in metal-working shops. For instance, deep cuts are taken from test logs with heavy feeds, a condition found primarily when machining exceedingly large forged shafts. However, by far the largest number of

[6] The Texas Company, New York, N. Y.

[7] Engineer, Warner and Swasey Company, Cleveland, Ohio. Mem. A.S.M.E.

hours in industry are spent in finishing forgings or bars which are but little larger than the dimensions of the finished work.

Two conditions are generally encountered in production shops when taking roughing cuts. First, the chip generally is hardly more than from $^1/_8$ to $^1/_4$ in. deep. Second, scale is generally being cut at some part of the cutting edge. When cutting "black" steel with carbide tools for instance, the conditions of wear of the cutting edge are quite different from those found when cuts are taken on test logs without scale. This is true with tools of high-speed steel as well, although the difference is not quite as pronounced.

It would seem, therefore, in the first place, that tests for roughing cuts, to be of practical value to the major part of the metal-cutting industry, should be within the range of depths of cut mentioned by the writer and with such feeds as are practical on the average job. Second, it would be highly desirable to take all cuts on the outer or "black" surface of forgings or bar stock, or on the unmachined surfaces of castings so that true manufacturing conditions are being simulated. It would, of course, be expensive to use such material for test purposes only. However, by taking such test cuts on work which is borrowed for the purpose from regular production shops, it should be possible to approach true shop conditions without excessive material costs. In doing such work, either bar stock or forged units could be roughed out to within $^1/_{64}$ in. of final size to be refinished and sized by the owner after the material has been returned from the laboratory. Thus, there would be a reduction in manufacturing cost to the owner of such material which might make up in part at least for the added expense of handling and shipping.

The authors have confined their work, as reported in the paper, to speeds and feeds on the practical side, and therefore their findings should be a valuable and usable contribution to the art of metal cutting. It would have rendered their findings even more valuable if they had also confined themselves to the cutting of "black" stock. Perhaps this suggestion will help to keep future work of this nature on such a practical basis.

According to the authors' findings it would seem as if colloidal graphite could find a definite field of usefulness in the art of metal cutting. It is hoped that the oil companies will take this lead and will prove to the industry whether or not the added expense will be warranted. The authors point out that a more expensive fluid will readily pay for itself. Could Professor Boston show how the added expense of Oildag would be justified in a similar comparison?

The question of machine-tool lubrication is a vital one, and even though plain water might be the best cutting fluid under certain conditions, the damage done to the high-priced machine tool through corrosion and lack of lubrication would prohibit its use. The authors state that the superior soluble oil may at times not be used because it does not permit of adequate lubrication of an expensive machine tool. Would the addition of Oildag overcome this drawback? It would be of value to run wear tests simulating machine-tool conditions to determine the lubricating value of colloidal graphite in soluble oils.

A further question requiring an answer is whether the addition of colloidal graphite might not affect favorably the cutting of threads with taps and die heads where at present the heavy sulphurized-base oils are considered as being superior.

It would be helpful if there could be added below Table 3 a statement explaining such symbols as A-1-A or A-4-O.

O. L. Maag.[8] It is apparent from the data submitted in the paper that the cutting-fluid problem is more complex than one would think without intensive study. The fact that so many different fluids are used on the same type of product indicates that the type of cutting fluid to be used depends on such items as quantity and quality of work desired. The authors have summed the problem up quite well when they say: "Real economy lies in the selection of that cutting fluid which will do the job producing the best quality, the greatest production or both."

[8] Lubrication Engineer, The Timken Roller Bearing Company, Canton, Ohio.

Depending on whether a roughing job is being done or whether a close tolerance and good finish is desired, one fluid will show up better than another. As intimated, the type of steel also has an effect, and the writer believes that data on 4615, 52100, and 3312 S.A.E. steels should have been given in addition to the data on 2345 and 3140 S.A.E. steels, since they are largely used for such units as bearings and gears. Also, to cover the subject more completely, data on different tool steels should be developed. Likewise, it would be interesting to know the heat-treatment each of the steels machined received, since this factor will have much to do with the tool life, as well as the type of coolant used.

The writer's experience indicates that for close tolerances and good finish, oils are more desirable than water solutions. With oils there is no difficulty of sticking slides, the machines are kept tighter, and they run smoother and freer than when water preparations are used. Naturally, you do not obtain as much cooling as with water; however, this can be materially helped by the use of artificial cooling. It would be desirable if the authors could present data on the benefit of artificial cooling, holding the fluids to a definite temperature of approximately 80 F.

Data might well be made available on the film strengths of the compounded lubricants, since a number of companies are already standardizing their sulphurized and chlorinated cutting lubricants by checking them for film strength and holding this property to a definite figure. It is conceded quite generally that the good properties of this type of cutting fluid depend on its film strength, which may be determined on the Timken lubricant-testing apparatus.

Since straight chlorinated compounds of definite chemical structure are entering the cutting-oil field, it would be valuable to have data on such compounds as chlororetene, chloronaphthalene, chlorodiphenyl, and hexachlorethane.

The data given on colloidal graphite are quite interesting. Further, it is likely that they could be duplicated with other substances such as molybdenum sulphide, if there were a practical way of holding them in suspension. In plants where large amounts of cutting fluids are used, methods of reclaiming and reusing the coolants must be used for economic reasons. In service, oxidation products and acids are developed which tend to throw colloidal compounds out of balance, with the result that on settling or centrifuging, graphite and similar substances are separated from the cutting fluid. It is likely for this reason that such combinations have not worked out practically. The fact that the authors obtained only 3 per cent settling of graphite after the mineral oil and graphite had stood for three weeks can likely be accounted for by the absence of any petroleum acidity. If the oil had been used long enough to develop oxidation products as well as petroleum acidity before standing, the settling out would very likely have been much higher.

The writer believes that data such as obtained by the authors are quite valuable, and more should be obtained, so we may have a broader general knowledge of cutting and cooling compounds. However, due to such factors as individual operating conditions and local operating requirements, modification of any specific practice will frequently be found necessary.

B. E. Fleming.[9] The tests covered in the paper are confined as far as the writer can observe, to cutting operations with a straight turning tool, which might be comparable to a box-milling

[9] Lubrication Engineer, Shell Petroleum Corp., Milwaukee, Wis.

or cut-off job. It is known that this type of work comprises only a small percentage of automatic screw-machine, turret-lathe, and hand screw-machine work. The writer tried colloidal graphite on a Landis tangential die when cutting standard threads on wrought-iron pipe. The results were not as satisfactory from the standpoint of tool life or quality of thread as those obtained when using a blend of 15 per cent lard oil with 2 per cent added sulphur and mineral oil, which had a viscosity of 200 sec at 100 F.

The writer is obtaining excellent results with $1^3/_4$ per cent added sulphur to paraffinic oil of 150 sec viscosity at 100 F when this oil is used on general automatic screw-machine work cutting alloys of the following S.A.E. series: S.A.E. 3100 with .15 to .45 per cent carbon, S.A.E. 2300 with .15 to .45 per cent carbon, and S.A.E. 4100 and 4600 with .30 to .50 per cent carbon. The sulphur was added to the oil at a temperature high enough to keep it in suspension, but low enough to prevent discoloration. The finish blend is very agreeable to handle, it has no ill effects on the machine parts, and is hygienically ideal. This blend, will of course, discolor parts containing 30 per cent or more of copper. The writer finds that this blend has a decided advantage in that it facilitates inspection of the work during and after machining. It drains readily from the work and chips, thus favorably affecting oil consumption. However, such a material is not suitable for most broaching (draw), tough reaming, or thread chasing on soft tough metals. It seems that on such operations additional oiliness of the fixed oils is needed. Perhaps the authors can give reasons for this fact.

The writer would like to comment on the cost of the colloidal graphite used by the authors in their tests. Ordinary mined graphite is not suitable for use with cutting fluids. Is this not correct? The cost of good colloidal graphite is almost prohibitive when considered as a general cutting-oil compound in the shops where the writer is employed. The results would have to be very outstanding to warrant its consideration on even some of the most bothersome operations. From a practical point of view, most shops prefer to use the least possible number of cutting-oil blends, and some shops sacrifice on some operations in order to standardize and simplify cutting-oil requirements. This being the case it would be difficult to introduce special oils for some of the operations because it would be too expensive to use as a general cutting fluid.

The writer would also question the practicability of the colloidal graphite from the point of view of its performance in chip centrifuges and other reclamation devices. Judging by the behavior of such a blend during other experiments, it would seem that a great loss of the graphite constituent would occur during the reclaiming operations. This being true, the cost would be still further increased, and the concentration of the blend would be more or less questionable as more or less reclaimed oil was returned to service in the machines.

In machining alloy steels, the writer's attention has been attracted many times by the importance of the physical characteristics of the metal. It is of course true that cutting oils and coolants play a part that is too important to be overlooked in obtaining suitable tool life and finish; the condition of the metal is also a factor which must be considered if good ultimate results are to be obtained. The writer is of the opinion that there is some relation between the physical and chemical characteristics of the coolant or lubricant, and that to produce good cutting results the chemical and physical characteristics of the steel being machined must be considered. Heat-treatment to produce the proper grain structure, density, and suitable hardness of the steel being cut very probably has a definite effect upon its machinability.

The writer would be interested in learning of any tests of which the authors have knowledge which indicate the machinability of some alloys after heat-treatment. He would also be interested in what effect grain structure and physical condition of the steel have on its machinability and on the selection of the cutting fluid.

Maurice Reswick.[10] We in the oil industry, are deeply interested in the investigations of the A.S.M.E. Special Research Committee on Cutting Fluids. It helps us to visualize what the requirements of the industry are and points out the direction in which development of new products should be carried on.

From a practical standpoint, tool life is the most important factor in metal cutting. The failure of one tool on an automatic lathe results in delays which render ineffective the other tools on the same machine although they may still be in good cutting condition. Data on tool life versus cutting speed is therefore the most practical evaluation of cutting fluids.

The effect of colloidal graphite in cutting oils is of considerable significance. It appears that the introduction of solid particles of minute size in a mineral oil contributes to longer tool life and makes possible higher cutting speeds. Further investigations may disclose that other materials than graphite will give similar results provided such materials can be maintained in the oil in a condition approaching a colloidal suspension.

The presence of the solid particles in the colloidal suspension probably prevents metal-to-metal contact between the chip and the tool, acting as an antiweld medium. In other words, when the oil film breaks down under the pressure of the chip, the solid particles perform the function of preventing intimate contact.

The present tendency is toward transparent cutting oils, which facilitate inspection of the work while it is in the machine. Graphite has the disadvantage of rendering the cutting oil black in color and opaque.

Cutting oils compounded with animal fats and impregnated with sulphur are more chemically active than straight mineral oils. During continuous service and recirculation, it is possible that certain changes take place in the composition of the oil through the formation of iron soaps by interaction with the fats, and iron sulphides by interaction with sulphur. This brings up the question whether or not used cutting oils are more effective than fresh cutting oils.

Perhaps Professor Boston and his associates could give us some data at some future date on tool-life tests using an oil as received from the refinery and also on the same oil after it has been in service in regular production work for a reasonable period of time.

Authors' Closure

Many questions have been asked relating to the use or selection of cutting fluids. Some of these questions have reference to the practical application, while others suggest problems of research from which knowledge may be gained on the theory of cooling and lubrication. These questions are so extensive that a short supplementary bibliography on cutting fluids is appended to this closure for reference.

Mr. Adams presents a very interesting discussion relating to the functions of cutting fluids. From many experiments, as conducted by the authors, to determine whether a cutting fluid acts better as a coolant or lubricant, it is felt that cooling is of more importance than lubrication in the average metal-cutting operation, particularly in turning. In cutting ductile metals, a built-up edge is formed along the cutting edge of the tool over which the chip slides as it is separated from the work. This built-up edge is trapped in this position by force components which reach a magnitude of 300,000 lb per sq in. at a cut of, say, 0.025 in. feed. For lighter cuts, the pressure may reach 500,000 lb per sq in. It does not seem possible that a cutting fluid can penetrate between the chip and tool against such pressure. The

[10] Lubrication Engineer, Standard Oil Company of New Jersey, New York, N. Y. Mem. A.S.M.E.

fact that water, which is a better refrigerant than an oil, gives a higher cutting speed for any tool life than most oils, again would indicate that cooling is of most importance as far as tool life or tool wear is concerned. The authors have found that the tool life for a given cutting speed when turning a steel bar at different temperatures is greatest for the lowest temperature of the test log. These temperatures have been carried to 12 F below zero. The authors believe that the cooling of a tool by an air blast at different temperatures in order to eliminate lubrication would lead to similar results, but as yet they have not tried it. It would seem that lubrication at the low temperatures is not much different from that at the slightly higher temperatures, so that the results must be due to cooling. At the same time, it is recognized that lubrication is a variable factor in the problem.

In running drilling tests in which a hole of 1 in. diameter is drilled through a piece of steel in the form of a cube 1.5 in. on a side, in which the drill and work are submerged in a constant volume of liquid, the authors have been unable to find any appreciable or consistent difference in rise in temperature of the cutting fluid with different types of cutting fluids. The lubricant, although a poor coolant compared with water, may prevent the generation of heat, and therefore has less heat to absorb. Torque and thrust values at the point of the drill were also obtained, although the data have not been studied sufficiently to arrive at final conclusions. It would be expected that the lubricant producing the least torque and thrust, thereby doing the least work presumably because of lubrication, would produce the highest cutting speed for a given tool life. From one set of tool-life tests in turning steel, the authors have found that the tangential cutting force on the tool for a given group of cutting oils is directly proportional to the speed, that is, that cutting fluid which produces the lowest cutting force gives the lowest cutting speed for a given tool life, just the opposite of what might be expected.

The authors do not agree with Mr. Adams' description of tool failure. It appears from his question No. 4 that the tool in turning steel fails by becoming dull on the cutting edge. Actually, it is the cutting edge that is the last thing to fail at the time breakdown occurs. Further, the generation of heat between the tool and work is greatest at the beginning of the cut when the tool is sharpest. As the tool is cupped on its face by the abrasive chip, the cutting force and temperature are reduced and both become a minimum just before the breaking off of the acute cutting edge formed by the tool flank and groove.

Mr. Adams' summarized suggestions are excellent. Some of these have been carried out, but unfortunately the results, as have been outlined previously in this closure, do not fall in altogether with the logic. Therefore, it appears that still more work must be done before a complete understanding of cutting fluids is gained and it becomes possible to specify the theoretically correct cutting fluid for each class of work.

Mr. Ernst's discussion as to the use of cutting fluids and their action on chip formation is in agreement with the authors' opinions. However, confirming laboratory or practical tests are still lacking to give us a complete understanding of the subject. The authors have found that, if a good machined finish is desired, the built-up edge should be made small. This is accomplished singly or jointly by taking a light cut, operating at high speed, using a tool having considerable rake, and applying the correct type of cutting fluid. However, the authors believe that the influence of speed in many cases overshadows all of the others.

Mr. Szymanowitz has presented the subject of cost in an interesting light, showing that the cost of a cutting fluid may be increased appreciably and yet, considering all of the equipment involved in the operation, the total increased cost in per cent is small in comparison with the increased production.

It is interesting to note, as indicated by Mr. Barber, that some manufacturers of cutting oils are carrying on fundamental research in the use and action of cutting fluids. Reference is made in his second example to the flowing of the cutting fluid into the tiny crack preceding the cutting edge of the tool. Actually, when cutting ductile metals, the authors believe that there is no crack preceding the point of the tool, inasmuch as this space is filled with the built-up edge under tremendous pressure. The results of his tests on surface finish are extremely interesting. It is difficult, however, to understand that surface finish is not better at the very high speeds in spite of any cutting fluid used. Mr. Barber also brings out the important point that the performance of cutting fluids will vary with the type of process involved. Mr. Barber's three questions may be answered as follows:

1 Most of the experimental points representing cutting speed and tool life for a uniform test log and well-prepared tools fall within the thickness of a line. Frequently, at the beginning of tests some tool bits are found to give consistently high or low results, in which case they are discarded. Also, some cutting fluids have been found to give more consistent or uniform experimental data than others.

2 Tool temperature measurements were not made concurrently with the tests discussed in the paper. They have been made, however, in other tests by the authors. A very definite correlation is observed between cutting temperatures and tool life. The higher the cutting speed, the higher the cutting temperature and the shorter the tool life. The authors have considerable data showing the relation between the cutting force, temperature, and tool life in turning steel, in which the toolwork thermocouple was used. One paper was presented at the Annual Meeting of the A.S.M.E. in December, 1934, but was not published. At this time additional work is being done along this line in which a thermocouple tool is being used to measure temperatures when cutting different materials or when cutting one material with various cutting fluids. These data are not yet ready for publication.

3 The method of determining tool breakdown has been described in an article on "Machinability of Steel" in the National Metals Handbook, 1936 edition. It was described further in another paper[11] by the authors. This paper[11] describes a preliminary and final tool breakdown. The preliminary tool breakdown, which occurs sometimes soon after starting the cut, involves the breaking off of one part of the cutting edge before the cupping has proceeded far enough to cause a general breakdown.

Preliminary tool failure may or may not cause a change in the finish on the work or a change in size of the work. It is manifest either by a burnished ridge on the shoulder of the cut or by a change in surface finish or both. The final breakdown is detected either by an increase in cutting force on a dynamometer or power on a wattmeter, or by the presence of a burnished surface on the shoulder of the cut. One skilled in running tests of this nature can, by watching the chips come from the work, tell amost exactly when the tool fails. In many tests the authors have found that the data from preliminary tool failures change only the constant C in the equation $VT^n = C$.

Mr. Lange has sounded the note of practical-versus-laboratory investigations in metal cutting. He points out how true manufacturing conditions may be simulated in the laboratory by taking one cut from black-surface forgings, after which the forgings could be returned to the manufacturers. This might be practical in a city such as Cleveland where schools are located close to industry. However, in Ann Arbor the situation is somewhat different. In turning forgings, the work would not always run

[11] "A Study of Cutting Fluids Applied to the Turning of Monel Metal," by O. W. Boston and W. W. Gilbert, Trans. A.S.M.E., vol. 158, November, 1936, paper MSP-58-10, pp. 685–695.

true and, therefore, there would be a variation in depth of cut. It would seem, however, that work of this nature could be done best by careful observation in the manufacturing plant.

Mr. Lange further points out that the paper indicates the possibility of using to advantage colloidal graphite in commercial cutting fluids. It was not the authors' intention in presenting these data to promote the use of colloidal graphite as an ingredient of commercial cutting fluids, but rather to show some results of its use. Inasmuch as these results show superior performance, it is felt that it would be quite possible to prepare cutting fluids containing colloidal graphite which could be adapted to various processes and metals and show profits in spite of the high cost of graphite. Mr. Szymanowitz gives, in his discussion, data on the cost when using the expensive graphite. It is seen that, even with the high cost of graphite, the total cost over that when plain oil is used is only 3 per cent with an increase in production of over 25 per cent, whereas the sulphurized mineral oil shows an increase of 1.68 per cent in total cost over plain oil with an increase in production of 12 per cent.

Since this paper was presented, the authors know of numerous cases where colloidal graphite has been tried out on commercial work. Some of these instances have resulted in failure, inasmuch as the cutting fluid has not been adapted to the colloidal graphite, or the resulting mixture to the work. Undoubtedly there are numerous difficulties of a chemical and mechanical nature to be overcome in applying colloidal graphited cutting fluids commercially. However, the authors believe that these can be overcome.

Mr. Maag raises the question as to the use of colloidal graphite in various oils. Petroleum acidity will develop as the oil is used, and presumably will cause the colloidal graphite to settle out. This point also has been raised by Mr. Reswick and was discussed verbally by Mr. Oldacre[12] at the time of the meeting. It is pointed out in the paper that the colloidal graphite did not function satisfactorily in two of the three emulsions used. This in itself indicates the need for a correct type of soluble oil to carry the colloidal graphite, should it be used.

Mr. Fleming raises the question as to the practicability of using colloidal graphite because of its performance in chip centrifuges and other reclamation devices. Undoubtedly, the cutting fluid should be analyzed frequently in order that the graphite content be maintained above the minimum value found useful. Mr. Fleming also raises the question as to the relation between the physical and chemical characteristics of the cutting fluid and that of the physical and chemical characteristics of the steel being machined. This is a subject deserving a great deal of attention. Much is being done along this line at the present time. Inasmuch as the paper does not include this wide field for discussion, it is felt that the present space should not be covered by such a lengthy discussion. Many articles have been published on this subject, and the authors refer to (1) and (4) in the Bibliography at the end of this closure.

Mr. Reswick raises several additional questions, one of which involves the performance of a new oil as compared with the same oil after being used for some time. In order to avoid the possibility of error, the authors have constantly used fresh oils in their tests. It has been found true that as the oils change or develop acids their performance will be different.

Undoubtedly, the authors have not answered all questions that have been raised. Inasmuch as they are almost constantly engaged in experimental work with cutting fluids, they would be very happy to have any one interested communicate further with them.

Equipment and Problems in Handling Oil as a Locomotive Fuel[1]

M. A. Herzog.[2] The writer was interested particularly in the author's presentation of the evils of open steaming for heating fuel oil, and his emphasis on the harmful effects of water in oil. This is a phase of fuel-oil handling which has been neglected too much by many practical railroad men. Locomotive oil tanks on the St. Louis-San Francisco Railway are equipped with both open and closed heaters, and the engine crew is instructed to use the open heater only to break up any accumulation of sludge or sediment on the bottom of the tank which might interfere with the free flow of oil to the burners. In spite of this it is quite usual to find from 5 to 8 per cent of water in samples taken from locomotive oil tanks. In cases of steam failures blamed by engine crews on poor oil, investigation has shown that the oil contained from 20 to 30 per cent water. This water was introduced from heaters either in the terminal fuel-oil storage tanks or in the locomotive tank. No evidence has ever been found of fuel oil being shipped by the refiners with more than a trace of water.

The presence of water in fuel oil not only reduces the heat content proportionately, but as stated by the author it also results in loss of combustion efficiency and may cause serious difficulties due to increase in viscosity and foaming of the oil when heated. It is generally believed that water in heavy fuel oil will settle to the bottom when the oil stands undisturbed, and can then be drawn off. With most fuel oils, this is far from true. Water introduced into fuel oil by the condensation of steam from a heater will usually form a permanent emulsion with the oil, and will separate only slightly or not at all after days and weeks of standing. The writer has seen such emulsions which contained over 50 per cent water, and which did not separate appreciably after standing for more than a month. This reluctance of water to separate is aggravated by the low gravity of present-day fuel oil, much of which is of practically the same weight as water, so that there is no tendency for the water to settle out.

Water in locomotive fuel oil is definitely harmful, and since it cannot be removed after it is in the oil, the only remedy is to keep it out. This can be done by eliminating open steaming and providing ample closed-heater capacity, with possibly some mechanical device for agitating the oil to prevent accumulation of sediment. It is probable that if water were kept out of the oil, bottom sediment and sludge accumulation would be negligible.

Elimination of open steaming means that during cold months heavy fuel oil must be shipped in tank cars equipped with closed heaters in good condition. An increasing number of fuel-oil tank cars are being so equipped, but it is still all too usual to receive fuel oil in cars not provided with steam coils or with the

[1] Published as paper RR-58-2, by Guy M. Bean, in the August, 1936, issue of the A.S.M.E. Transactions.

[2] Chief Chemist, St. Louis-San Francisco Railway, Springfield, Mo.

coils leaking badly. In either case, it is impossible to unload a viscous oil without first mixing it with a considerable amount of water in the course of heating. Refiners should realize that shipment of fuel oil in such cars is causing the railroads considerable trouble and extra expense in cold weather.

J. C. Martin, Jr.[3] The oil-burning locomotive of today is practically the same as it was 25 years ago, with the exception of one principal change, namely the method of firing, whereby the burner was taken from the rear of the firebox and situated at the front or flue-sheet end so that the injected fuel could be discharged in a direction opposed to the draft. Today, and for the past 20 years, this has been standard practice; but outside of this highly beneficial change, which saved fireboxes from the punishment of localized heat, no other than minor changes have been made in the equipment, furnace design, or drafting of an oil-burning locomotive.

The firebox of a locomotive, even in the largest types, presents a very restricted space in which to burn a gaseous fuel, such as atomized fuel oil. Because of this fact, and because intermittent conditions from maximum to minimum firing rates often change within a relatively few minutes, ways and means must be devised to burn the fuel in the most efficient manner. When it is considered that the fuel oil must be burned in the modern wide-firebox engine at the rate of from 10 to 12 gpm, and preferably with a single fuel-oil burner to avoid complications in equipment, some idea can be had by combustion engineers not specializing in locomotive boilers as to the exacting conditions obtaining.

Although the present practices of burning fuel oil in a locomotive firebox have proved to be reliable these many years and capable of getting locomotives over the road expeditiously, constructive criticism is always in order, and to this end the writer's remarks are directed.

A major item that demands attention is the character of the fuel oil now available and to be furnished by the refineries in the immediately following years. Present facilities on locomotives and at terminals have not been brought in line to meet the changed complex of the present-day cracked fuel oils. The railroads have not yet sensed to a sufficient degree the fact that changes must be made if the maximum efficiency is to be obtained from cracked fuel oil for steam-generating purposes.

There is nothing particularly unusual about the problem. All combustion engineers are fully aware of the fact that these cracked fuels must be broken up or pulverized, so to speak, so that they will present the greatest possible carbon content for oxidation by the air introduced into the firebox for combustion purposes. The logical thing to do in effecting this is to provide adequate heating of these cracked oils. This should be done at three points. First, they should be heated to approximately 90 F to permit them to flow freely to the fuel-filling cranes and into the locomotive tank. Second, they should be heated to approximately 120 F in the locomotive tank so that they will flow freely through flexible conduits and pipe connections to the locomotive side in sufficient volume to meet maximum firing rates. Third, they should then be heated at the locomotive side with the most efficient type of heating device possible so that it will leave the heater and pass to the burner at a temperature of not less than 200 F. This would mean a temperature at the burner point of not less than 190 F.

Present facilities for heating fuel oil on locomotives provide only the handed-down practice of a so-called superheater comprised of a $3^1/_2$-in. steam pipe 5 to 7 ft long jacketing the fuel-oil pipe to the burner. This was sufficient for top fuel oils, but is now inadequate with cracked fuel oils. What is needed is a heating facility capable of maintaining, without question, a higher temperature of the oil at the burner.

[3] Consulting Engineer, Combustion and Refractories, Los Angeles, Calif. Mem. A.S.M.E.

In regard to the temperature of the oil, this obviously should be varied to suit the character of the cracked fuel being received, particularly its flash point. Live steam for heating is advocated on account of its heat-exchange value as compared to the relatively low head with which the fuel oil flows from tank to burner by gravity.

It may be stated with certainty that, with economy of steam for heating considered and with a well-designed heat exchanger located in the same position on the locomotive as the present superheater, the temperature of the oil may be raised from the proposed minimum of 200 F to a temperature even 100 deg higher (flash point permitting) without any possibility of volatile constituents of the cracked fuel being lost. This higher temperature could be attained because the cracked fuel is usually boiled off in the refinery at temperatures far in excess of 300 F, that is, it was produced at temperatures varying from 600 to 800 F.

Another item of consequence to be considered in meeting the characteristics of the present cracked fuel oil is the adaptation of pressure on the oil to the burner. This should now be considered seriously since it would result in constant control of the fuel and uniform flow through the burner, and therefore aid greatly in the efficiency of combustion over the present gravity feed. This has not been done heretofore because of complication of equipment, lack of space, and no crying need until cracked oil took its place as fuel. With the advent of cracked fuel consideration should be given to the production of a simple system with a pressure-fired oil burner as a constructive improvement over the present gravity system of firing.

Steam-jet atomization for burners may well be continued as heretofore; but with a pressure burner in lieu of the present gravity-type burner the steam consumption for atomization will be materially reduced. Established practices show a steam consumption of 3 per cent for pressure burners as against a steam consumption of from 5 to 8 per cent with present standard locomotive gravity burners such as the Booth or Von Boden type, which are representative.

Mechanical atomization of fuel oil into locomotive fireboxes is yet a problem to be reckoned with. Tests along this line have proved to be disappointing, due to the delicacy of the apparatus, carbonizing of burners, and inability to maintain maximum rates of firing required with a single burner.

Reliability of apparatus is of paramount importance, and much research work must yet be done to make mechanical atomizing on a locomotive a success. However, there will always be a reward for effecting the successful mechanical atomization of fuel oil in a locomotive firebox, due to the elimination of steam as an atomizing element, as well as in increasing the volume of the firebox as a combustion chamber in which to burn gaseous-type fuel; for it will be clear to those concerned in this problem that the steam for atomizing is a noncombustible ga soccupying space in the firebox which could otherwise be utilized for increasing thermal efficiency.

Author's Closure

Mr. Herzog's comments on the importance of providing transportation, terminal, and locomotive fuel-oil-handling facilities that will preclude contamination of the fuel through the admixture of water are timely and accord fully with the author's ideas. These phases of fuel-oil handling are all too frequently overlooked and result in efficiency losses that aggregate to considerable amounts.

Too much stress cannot be placed on the need for careful study of all apparatus involved so that the fuel may be delivered to the locomotive furnace in the most suitable condition for

proper functioning, which means as free from moisture as is practically possible and at temperatures required for efficient firing.

While the higher percentages of water in fuel oil as quoted by Mr. Herzog are rather exceptional, the fact that they are encountered only stresses the importance of keeping them to a minimum. Properly designed indirect heaters can be provided in all heating phases that will suitably heat the fuel to the temperature required in each phase and their adoption will readily repay the involved cost in final efficiencies.

Mr. Martin's discussion fully bears out the author's idea both as to the need for providing means for separate heating of the fuel in the locomotive reservoir and final heating of the fuel to burning temperatures on the locomotive side.

There seems to be a definite lack of understanding, among many who are daily handling modern locomotive fuel oils concerning the great change in the fuel characteristics that have been brought about through modern refinery practices. It is important that every consideration be given to the needs for equipment changes that will meet these fuel changes. This involves study and experimentation with all heating problems, methods of delivery of the fuel to the burner, types of burners that will give the best atomization of the fuel, and finally careful proportioning and location of air-admission openings in the furnace.

Functions for Solution of Three-Moment Equation for Beam Columns With Nonuniform Loads[1]

H. M. Hansen.[2] The paper represents a convenient supplementary contribution to existing tables which, for different types of end conditions, transverse elementary and total loadings, give the influence on the slope at the end of an assumed simply supported beam with constant flexural rigidity. Since the author has computed the table on the basis of well-known theories and formulas in common use, the writer's discussion will be confined to the errors introduced by the substitution of an elementary concentrated load for a distributed load, when the element used is one tenth of the length of the span.

Using the same symbols as in the paper, we have

$$\psi_C = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL} - K\right] \ldots\ldots\ldots\ldots [1]$$

as the combined effect of an axial and a transverse concentrated load. By an integration it will be found that the function for a load, uniformly distributed over a distance $2CL$, can be written as

$$\psi_D = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin CjL}{CjL} - K\right] \ldots\ldots\ldots [2]$$

in which KL is the distance to the center of distribution. For a distribution of one tenth of the span, or $C = 1/20$

$$\psi_D = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin (jL/20)}{(jL/20)} - K \ldots\ldots [2a]\right.$$

The value of the distribution factor $(20/jL) \sin (jL/20)$, between $jL = 0$ and the critical condition $jL = \pi$, varies from unity to 0.9957. The error due to the substitution of a concentrated load for a uniformly distributed load is therefore, in this case, small and can be neglected for ordinary purposes.

TABLE 1 PER CENT DIFFERENCE[a] BETWEEN ψ_C AND ψ_D

jL	Per cent difference when $K = 0.1$	$K = 0.5$	$K = 0.9$
0	+0.25	+0.33	+1.32
1	+0.26	+0.34	+1.24
2	+0.29	+0.35	+1.00
3	+0.38	+0.39	+0.51

[a] Per cent difference = $100\,[1 - (\psi_D/\psi_C)]$.

Table 1 of this discussion gives for various values of K and jL the difference in per cent between function ψ_C, the tabulated value, and ψ_D from Equation [2a].

The effect of a load gradient on the elementary function ψ can in part be investigated by considering a trapezoidal loading, the exact expression for which can be shown to be

$$\psi_T = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin CjL}{CjL}\left\{1 + \frac{3(G-K)}{C}\cot KjL\left(\frac{1}{CjL} - \cot CjL\right)\right\} - G\right] \ldots\ldots\ldots [3]$$

where, as before, $2CL$ represents the distribution, KL is the distance to the center of distribution, and GL is the distance to the center of gravity of the load; GL and KL are measured from the same support and have the same positive direction. Analytically

$$G = K + \frac{C}{3}\,\frac{p_1 - p_2}{p_1 + p_2}$$

where p_1 and p_2 are the intensity of loading at the ends of the trapezoid.

If investigating one of the more extreme cases such as a triangular loading, Equation [3] reduces to

$$\psi_\Delta = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin CjL}{CjL}\left\{1 \pm \cot KjL\left(\frac{1}{CjL} - \cot CjL\right)\right\} - \left(K \pm \frac{C}{3}\right)\right] \ldots\ldots\ldots [3a]$$

where the upper sign is used for $G > K$, the lower for $G < K$. The gradient factor may be given a more convenient form by substituting for $\cot CjL$ the first three terms of its series, and the equation can, for all practical purposes, be written

$$\psi_\Delta = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin CjL}{CjL}\left\{1 \pm \frac{CjL}{3}\left(1 + \frac{(CjL)^2}{15}\right)\cot KjL\right\} - \left(K \pm \frac{C}{3}\right)\right] \ldots\ldots\ldots [3b]$$

In this case, where $C = 1/20$, the first two terms will suffice and the equation takes the particular form

$$\psi_\Delta = \frac{6}{(jL)^2}\left[\frac{\sin KjL}{\sin jL}\,\frac{\sin (jL/20)}{(jL/20)}\left(1 \pm \frac{jL}{60}\cos KjL\right) - \left(K \pm \frac{1}{60}\right)\right] \ldots\ldots\ldots [3c]$$

Applying this Equation [3c] to different values of K and jL, the per cent difference between ψ_c, the tabulated value, and ψ_Δ from Equation [3c] is shown in Table 2 of this discussion. While the elementary errors under certain extreme conditions are rather high, as shown by Table 2, the error occurring from the use of the author's tables on a triangular loading over one half end of the beam amounts to 0.3 per cent of the theoretical value.

[2] Assistant Professor of Engineering Mechanics, University of Michigan, Ann Arbor, Mich.

TABLE 2 PER CENT DIFFERENCE[a] BETWEEN ψ_C AND ψ_D

jL	Per cent difference when $K = 0.1$		$K = 0.5$		$K = 0.9$	
	$G>K$	$G<K$	$G>K$	$G<K$	$G>K$	$G<K$
0	—16.1	+16.6	—0.8	+1.4	+16.3	—12.0
3	—15.7	+16.5	—0.3	+0.5	+16.3	—15.3

[a] Per cent difference = $100\ [1 - (\psi\Delta/\psi C)]$.

For any distributed loading usually encountered in practice it seems, therefore, reasonable to expect that the use of the author's tables will give results which are consistent with the usual expected accuracy of other required data.

On the other hand, the results so obtained can, in most cases, be expected to vary about 0.5 per cent with the theoretical value. It seems, therefore, not justified to use more than three significant figures in the author's tables.

Welding Heavy Machinery[1]

F. O. Leitzell.[2] The authors have presented the problems encountered in the proper production of heavy welded machinery in a clear, concise, and excellent manner. Too many times the problem of designing welded machinery has been approached without the proper thought being given to the advantages and higher efficiencies obtainable from welded construction. Many designs have been made by simply replacing welds for rivets and bolts or cast construction, with no consideration given to weight saving or proper design. The authors have pointed out clearly that to obtain full advantage of welded construction one must take into account the shortcomings of riveted and cast construction, and be able to substitute therefor welded constructior where it can be applied with greatest advantage. Welding is not a cure-all, and the authors recognize this fact. However, there are a few points in the paper which can be stressed by additional discussion.

It is true that thick and thin members can be welded together and various metals can be combined in one piece by welding, but when this is done care must be used so that undue warpage will not occur, due to welding or to final stress relieving if this is necessary. The authors have mentioned that different metals may be welded together providing their coefficients of expansion are sufficiently similar so that undue stress is not set up when the welds cool.

In regard to the peening of welds in the construction of welded machinery, the writer believes that there are many places where it is advantageous to peen the various layers of weld, not to hide porosity or other defects, but for the proper working of the metal. This is especially true where extremely heavy sections are welded to light sections. Stresses are set up in this case and peening is a decided advantage. In other cases, light peening of the various layers removes scale and slag and leaves a clean surface for the succeeding bead. Furthermore, peening has a tendency to decrease warpage regardless of whether or not the finished piece is stress relieved by heating.

The authors' discussion of stress relieving by heating is excellent. The results required of welded machinery are so different from pressure vessels that the writer agrees with the authors when they state that no definite hard and fast rules of procedure can be laid down. However, the results desired in either case are the same, that is, a soft ductile weld with as nearly the same properties of the parent metal as it is possible to obtain. Where the various parts are of different thicknesses, the process of heating and cooling can be set only from experience in order to obtain ductile welds with a minimum of warpage.

The Electric Welding of Monel and Nickel[1]

P. R. Kosting.[2] The writer wishes to take exception to one statement made by the authors. This statement, found at the end of the first paragraph under the subtitle "Quality and Physical Properties of Deposited Metal" concludes with the phrase: ". . . . . . yield strengths of welded joints are still of little value, except when all-weld-metal specimens are used."

The engineer of today is using as the basis for his calculations, yield-strength values to a greater extent than his predecessors. This is particularly fortunate in the case of the common nonferrous alloys, the yield strength of which can be varied to a much greater extent than the tensile strength by combinations of cold working and annealing.

In the case of monel-metal plate, tensile strength is lowered less than 8 per cent by controlled annealing, while yield strength 0.00 per cent set (P.L.) is lowered 40 per cent. When welding monel there is an annealing effect adjacent to the weld. This heat-affected zone does have considerable influence on the properties of the welded joint. Indications are that the greater the electrical energy used in the arc for satisfactory welding, the less the number of layers of weld metal required and the lower the strength of the weld. The technique of determining yield strength of nonhomogeneous materials such as welded joints is not yet satisfactorily worked out. Using specimens that permit true axial loading and using sensitive extensometers, yield strength 0.00 per cent set (P.L.) of joints can be varied 30 per cent approximately without affecting tensile strength when specially annealed. It is therefore necessary to measure yield strength, especially for sets of lower percentages in order to follow the effects of varied manipulations. When using welded nonferrous metals the yield strength is very important.

Author's Closure

The authors agree with Dr. Kosting on the point he raises that yield strengths are being used more widely in machine-design calculation. There is, however, no full agreement on what a yield point is, for it is necessary to indicate the per cent set at which the yield point is taken, i.e., 0.00 per cent, 0.05 per cent 0.2 per cent, 0.5 per cent, or 0.75 per cent set.

American Hydraulic-Laboratory Practice[1]

Robert W. Angus.[2] The author has given an all too brief review of the hydraulic laboratories and hydraulic-laboratory practice in America. So far as the writer knows, he is the first Freeman Scholar to spend his entire time on this continent and he has used it very profitably. What Dr. Freeman did for Europe in his "Hydraulic Laboratory Practice," Mr. Hooper has done for America on a much smaller scale.

Some omissions are bound to occur and this is true regarding the laboratories for studying pumps, as these are fairly numerous. The author does not mention the new pump laboratory of the Dominion Engineering Works in Montreal, which has done some useful experimental work.

[2] Professor of Mechanical Engineering, University of Toronto, Toronto, Ontario, Can. Mem. A.S.M.E.

For turbine testing, and river and hydraulic structures, a laboratory located on a natural stream has many advantages, particularly in the way of having the water in a calm state as compared with that from pumps which cause turbulence that is hard to damp out; the laboratory at Worcester is an example of the former.

The turbine-testing laboratories are all rather similar and the large volume of water used by the one at Newport News shows that the scale for the models need not be small. The writer has considerable experience with centrifugal pumps, most of which are run for test before being delivered; the smaller ones usually under the full-scale conditions, and the larger ones at reduced speed. In many cases the writer has found the test-floor results materially different from those on the installed unit, and as the shop tests were known to be accurate, it would appear that the characteristics of the pumps are very easily affected by the setting. Therefore, too much care cannot be used in duplicating the actual setting in the laboratories.

Duplicate pumps made at the same time in the same shop rarely have exactly the same characteristics, and there still appears to be a margin between the actual and predicted pump results that cannot be overcome by adjustable vanes, as in the turbine.

In view of the extensive notice given to cavitation testing, further comment here is unnecessary, but the writer was greatly interested, when he visited Sweden in 1935, to know that in one shop at least, cavitation runs were made on all model runners of new design, and the plants for which the turbines were being made were designed on the basis of the cavitation tests. The cavitation-research field has apparently only just been entered.

The glass trough is invaluable for open flow work. Last winter, at the University of Toronto, an extensive study was made, under the writer's direction, of the flow over a model of the dam at Abitibi Canyon in northern Ontario, and in the only data available from the power plant, the experiments corresponded remarkably well with the measured results at the dam. Such work is invaluable and gives accurate data for the designer.

The writer believes that where a river model has different scales for length, width, and depth, as in the case cited at Carnegie Institute of Technology, the interpretation of the results leaves room for much question. Two different scales are troublesome enough, but the third greatly increases the difficulties. The use of transverse metal fins to vary Kutter's n is unusual and would seem to change the flow conditions greatly, even though it produced the desired mean hydraulic gradient. The model should be a true copy of the prototype, the resistance being produced in exactly the same way in both, if the stream flows are to be comparable.

The author's statement as to the tendency to reduce the scale ratios by increasing the model sizes is interesting. Some years ago the writer asked a distinguished German experimenter what scales should be adopted in river flow work, and the surprising reply was, "Full size;" that is, the factors for reducing the model results are not, in his opinion, as definite as is desirable in this class of experiment. On the other hand, small-scale model turbines produce with remarkable fidelity, curves of efficiency, output, and speed which enable results on the prototype to be predicted accurately.

Author's Closure

The comments and additions by Professor Angus in regard to centrifugal pumps and laboratories devoted to their test are appreciated. In this connection it should be noted that Table 3 of the original article should be amended to indicate that pump testing was also being done at Cornell University. This type of work was found in progress there but mention of it was omitted accidentally.

The author desires to take this opportunity to thank the directors of the various laboratories visited. Their kindness and cooperation during the inspection trip were appreciated.

Fuel Panel Discussion on Cinder Catchers

At the Annual Meeting in December, 1936, papers dealing with various phases of the fly-ash and flue-dust problem were presented by ten authors. These covered methods for measuring the quantity of entrained dust in flue gases, types of apparatus for removing solid matter from flue gases before their discharge to the atmosphere, utilization of pulverized-fuel fly ash as aggregate for a new kind of concrete and the manufacture of a building block, and the cinder and fly-ash public nuisance. P. H. Hardie describes measurement methods that are applicable to different types of dust-separating devices. Apparatus described and the authors of the various papers are: Gas-scrubber installation at a plant of The Edison Electric Illuminating Company of Boston, M. D. Engle; spray-zone fly-ash eliminator at the New York Edison Company's Hell Gate Station, J. J. Grob; a device utilizing directional changes of flow in a fan impeller to separate dust from flue gases, H. F. Hagen; a scrubber that causes ash particles to impinge on wetted vertical carbon plates as the gas travels in a staggered path through the device, O. Craig; cleaning flue gases by electrical precipitation, C. W. Hedburg; a combination recirculator and controlled multicyclone, L. C. Whitton, Jr.; and a compound type of dust eliminator utilizing a concentrating chamber and a cyclone, S. Brown. J. R. James outlines the use of fly ash and crushed cinders as concrete aggregate by The Detroit Edison Company and of fly ash in manufacturing building blocks. W. G. Christy emphasizes the fact that the discharge of solids from stacks has greatly increased of late and that the public is demanding action.

Résumé of Methods for Measuring Flue Dust

By P. H. HARDIE,[1] BROOKLYN, N. Y.

EXTENSIVE development work on methods for measuring the quantity of entrained flue dust[2] in the gases of coal-fired plants has been reported by a number of authors. Many different types of apparatus, employing slightly different test procedures, have been tried. As yet, none of them has been approved by the A.S.M.E. Power Test Codes Committee on Dust Separating Apparatus, nor is any standard generally recognized.

This paper will discuss the more general types of apparatus with special reference to their application and limitations. No attempt will be made, however, to cover devices for measuring atmospheric dust pollution, such as the U. S. Public Health Service Empinger, Owens Jet Dust Counter, and Drinker Electric Precipitator. This phase of the subject is adequately covered in the U. S. Public Health Bulletin No.2 17, published in 1935.

Dust Measuring a Sampling Process

Due to the large volume of gas involved, the problem of measuring flue dust has resolved itself into a sampling process. The following important principles of sampling are recognized as necessary in order to obtain reliable results. First, samples must be taken from a sufficient number of points in the cross-section of a flue to represent the entire flow. Stern (1)[3] says that a point at which the average conditions prevail can be determined, and only a few samples need then be collected. Second, the samples must be withdrawn from the main stream without change in composition. Third, the dust must be separated without loss or contamination. Fourth, the size of samples withdrawn must be sufficient to permit determining the weight of the dust collected with reasonable precision, and the per cent of combustible and size analysis if these data are also objects of the test. Fifth, supporting data must be taken to permit weight averaging of the individual samples.

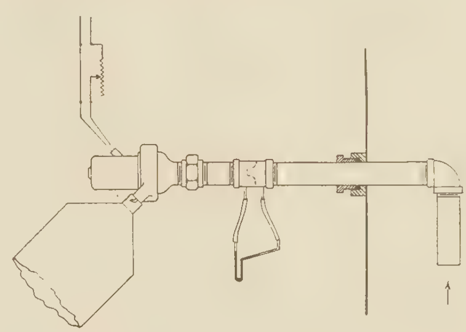

Fig. 1 A Simple Design of Dust Sampler With Filter Bag on Discharge Side of Blower

With virtually all types of flue-dust-sampling apparatus, the collection is accomplished by facing a tube into the stream and applying suction at the opposite end, with a dust-separating device located at some point in the sampling line.

A simple type of apparatus is shown in Fig. 1. The aerodynamics of dust particles dictates that that part of the moving stream drawn through the sampler must not change in velocity or direction at entrance to the sampler. Experimental results showing the errors caused by incorrect sampling velocities as determined by Fahrenbach (2), Zimmermann (3), and Caldwell (4), are reproduced in Fig. 2. Difference in size analysis of the dust being measured probably accounts for the disagreement between the three curves. Another error is introduced if the sampler does not face squarely into the gas stream. The measured values of this error (2, 3) have not been reproduced here, since it is a much less likely source of error, except where poor sampling

[1] Test Development Engineer, Brooklyn Edison Company, Inc. Mem. A.S.M.E. Mr. Hardie was graduated from the Alabama Polytechnic Institute with a B.S. degree in mechanical engineering in 1921 and later received his M.E. degree. He spent the following year at the Massachusetts Institute of Technology specializing in design and testing. He received early practical training with the Hardie-Tynes Mfg. Company, Birmingham, Ala., and was associated with the Westinghouse Electric & Mfg. Co. until 1926 as a steam-turbine designer. Since 1926 he has been engaged in power-station testing for the research bureau of the Brooklyn Edison Company, Inc.

[2] The term "flue dust" is applied to the solid refuse carried along with the gases of combustion and includes both cinders and fly ash.

Contributed by the Fuels Division and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., Nov. 30 to Dec. 4, 1936.

Discussion of these papers should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after this date will be returned.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] Numbers in parentheses refer to the Bibliography at end of paper.

locations are used. Samples should be taken in a long straight portion of the duct. A vertical run is preferable to a horizontal run as a sampling location.

Suction Apparatus

Several different devices have been used for producing the necessary suction for withdrawing the gas samples and overcoming the resistance of the separating device. Blowers of the vacuum-cleaner type are excellent when the resistance is not very high. They are used mostly with cyclone separators and with

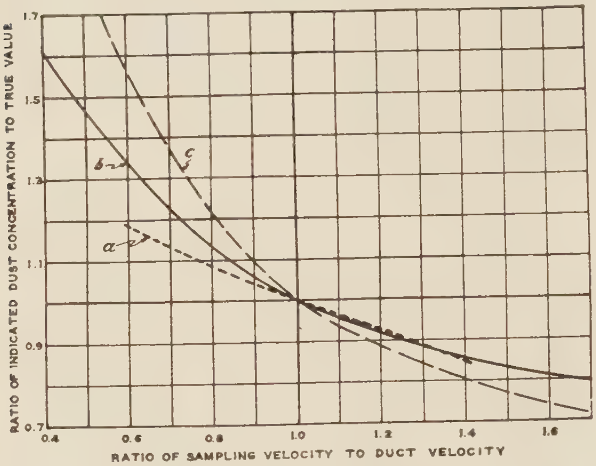

Fig. 2 Curves Illustrating the Magnitude of the Experimental Error Caused by Incorrect Sampling Velocity

(*a*, Plotted from data obtained by W. E. Caldwell and his associates with test equipment similar to that described in (4); *b*, Curves reproduced from Zimmermann (3) Fig. 14; *c*, Curves reproduced from Fahrenbach (2) Fig. 14.)

cloth bags located on the discharge side. For high resistance and large quantities, a steam siphon of the type used on condensers and pumps has been found to work well. Jacobus and Bailey (5) and Mackenzie (6) used a compressed-air ejector with a cloth-bag filter on the discharge side. The bag in this case had to be large enough to pass the compressed air as well as the sampled gas; otherwise, this method has much to commend its use. Water ejectors have also been used but mostly for small gas quantities and low resistance. Even laboratory types of reciprocating and rotary pumps have been used.

Determining Correct Sampling Rate

There are some investigators who prefer one of the automatic means of indicating when the correct sampling rate is being maintained while others prefer to measure the velocity in the duct and use the gas-metering device for indicating when this velocity is being maintained at the sampler inlet. In the latter case, traverses are made with a pitot tube and thermocouple, generally only just prior to each run, although check readings at intervals during the test can be made if found necessary. The disadvantage of this method is the inconvenience of converting velocity-pressure measurements into nozzle-differential readings. The gas pressure and temperature are generally lower at the nozzle and these differences must, therefore, be taken into account when determining what nozzle differential to hold.

Fig. 3 illustrates three different methods that have been used for automatically indicating the correct sampling rate. In Fig. 3*a*, two pitot tubes are used, one inside the sampler and one adjacent to the sampler tip. Equal velocity-pressure readings on the gages connected to the two pitot tubes indicate that the correct sampling rate is being maintained. This is probably the most accurate method for maintaining equal velocity. It has another advantage because the inside pitot tube serves as the gas-metering device. This method has two disadvantages: First, pitot tubes plug rapidly in a dust-laden gas stream; and, second, the sampler must be large to accommodate the pitot tube without too great a reduction in the gas-passage area.

The method shown in Fig. 3*b* utilizes two static-pressure tubes connected to a differential gage to indicate when equality of velocity has been attained. The outside tube is similar to a pitot tube but has no impact opening, and the other tube is connected to a piezometer ring located near the sampler tip. The static holes for this arrangement, as in the two-pitot-tube method, are likely to become clogged if they are made small enough to insure accurate readings. However, the size of the sampler tube has no limitation.

Fig. 3*c* shows how inverted-impact tubes are used to indicate the correct sampling rate. These tubes are less likely to clog, but the one facing into the mouth of the sampler may cause uneven flow of gas and dust into the sampler, unless it is exceedingly small in relation to the sampler size. The sensitivity of these inverted-impact tubes can be increased by flaring the ends.

Zimmermann (3) found automatic means for indicating correct sampling rates unnecessary, because the gas velocity in the ducts showed little change throughout a test. This has been the experience of other investigators (1, 4, 7). However, if the gas velocity fluctuates considerably in a test period, automatic means for indicating sampling rates would be desirable. Also, when an integrating gas meter is used for determining the quantity of gas sampled, automatic indication of adjustment has certain advantages.

Measuring Quantity of Gas Sampled

We come next to the means used for measuring the quantity of gas withdrawn as samples. Investigators are again divided,

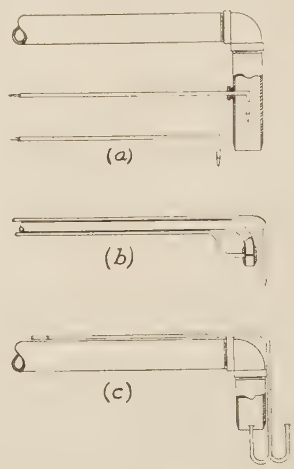

Fig. 3 Means Used to Indicate Automatically When Correct Sampling Velocity Is Being Maintained

(*a*, Equal velocity pressure on the two pitot tubes indicates correct sampling rate; *b*, Zero reading on differential gage connected to the two static tubes indicates correct sampling rate; *c*, Zero reading on differential gage connected to the two inverted impact tubes indicates correct sampling rate.)

this time between indicating and integrating types of instrument. Nozzles or orifice plates are the usual indicating type of metering device used. Stern (1) eliminated the nozzle by using the pressure drop through the cyclone separator, having previously obtained a calibration curve for pressure drop against flow.

A pitot tube located inside the sampler tube, as illustrated in Fig. 3*a*, is another indicating method. For the integrating method, the house type of gas meter has generally been used. Both indicating and integrating methods require gas pressure and temperature measurements to determine mass flow. The author, in a previous paper (7), described a method for maintaining a predetermined constant discharge pressure from all nozzles in a group, thereby reducing the number of readings and also simplifying regulation of flow and computation of results for multiple-sampler tests.

Mackenzie (6) described a simplified procedure in which no gas quantity measurements were made. With inverted impact tubes, similar to Fig. 3*c*, he maintained the correct sampling rate with the sampler located for an equal length of time at the center of several equal areas into which the duct was assumed to be divided. Then, from the quantity of dust collected, and knowing the sampler-mouth and duct cross-sectional areas, the total quantity of dust passing the section in a test run was computed by using the ratio of these areas.

The other test methods are based on determining the dust concentration[4] from which the total quantity of dust can be computed if the quantity of gas passing is known. In some cases, the total quantity of dust need not be determined because all that may be desired is the efficiency of the dust-separating

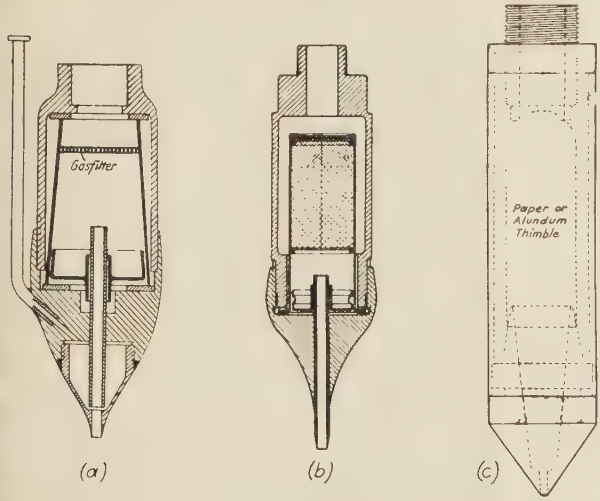

Fig. 4 Sampler Heads Containing Gas Filters

(The separation of the dust takes place inside the flue and the sampler, therefore, must be withdrawn to remove the dust; *a*, Design of head used by Zimmermann (3), which contains a Schott granular glass filter. The small tube on the side is the static-pressure connection for indicating the correct sampling velocity similar to that shown in Fig. 3*b*; *b*, Another design reported by Zimmermann (3), in which glass wool is used as the filtering medium; *c*, Design of head used by Research Corporation (11). Either a paper or alundum thimble can be used with this head.)

equipment. Since the quantity of gas is the same entering and leaving the separator, the efficiency can be computed from the dust concentration at the inlet and outlet without having to know the total quantities involved.

Dust-Separating Devices

A variety of devices have been used for separating the dust from the sampled gas. The separator is generally located outside of the gas duct, but some investigators have designed heads containing filters which are attached to the tips of the samplers. Fig. 4 shows three different types of head.

The paper-thimble and cloth-bag filters and cyclone separator are the three more generally used devices. Other less common devices are alundum, metal-screen, glass-wool, and Schott glass filters and the water-bubbling bottle. All of these methods have been made to perform reasonably well under certain operating conditions. No one means of separating the dust from the flue gas has been found entirely satisfactory for all operating conditions.

Paper-Thimble Filter. This device was perfected by Brady and Touzalin (8), and is generally spoken of as the Brady thimble. It has been used both inside and outside of the gas duct. When the gas temperature is high, paper thimbles will fail very easily. If the thimble is located outside of the duct, the sampled gas may be cooled sufficiently to eliminate this trouble. However, the gas can be cooled too much, thereby causing condensation on the thimble. A method of electrically heating the thimble casing to eliminate this trouble when the gas temperature is too low is used by a large steel company (9).

Due to the small gas-filtering capacity of these thimbles, they have been used almost entirely for pulverized-fuel installations, which do not require a large sampler because the dust particles are of small size. The diameter of sampler mouth used with these thimbles is generally $^1/_8$ or $^3/_{16}$ in., which is entirely too small to catch the large-size cinders produced in stoker-fired furnaces.

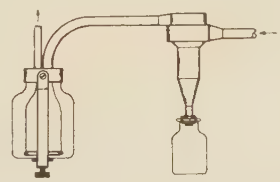

Fig. 5 Cyclone Separator and Cloth-Bag Filter in Series

(The main purpose of this combination is to reduce the tendency of the bag to give trouble when the cinder concentration is high. The cyclone can be made small because a high efficiency is not necessary. This design has been used by the Brooklyn Edison Co.)

Cloth-Bag Filter. Filters of this type are divided into two classes, those located ahead of the source of suction and those on the discharge side. Bags located ahead of the suction apparatus must be encased in an air-tight container, generally a glass jar, and are therefore limited in size. Bags located on the discharge side have no such limitation imposed on their size. However, they should not be made so large in proportion to the quantity of dust collected that an appreciable error is introduced when determining the weight of dust, either by emptying and weighing or by weighing the dust in the bag and then subtracting the tare weight of the bag.

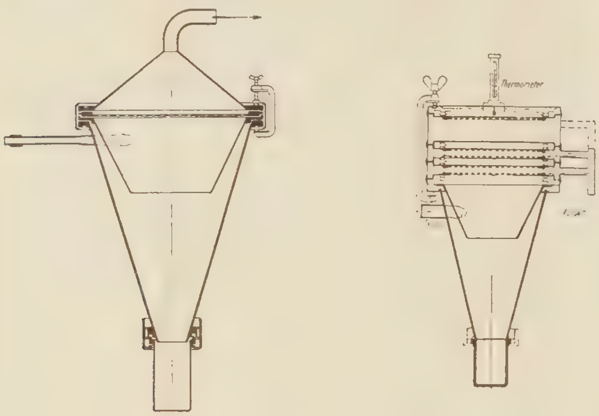
Both wool and cotton cloths have been used as material for the bags. The former is more expensive but will withstand a higher temperature. Even asbestos bags have been tried, but they are not considered very satisfactory. The cloth-bag filter can be made for large as well as small-size samplers; for a maximum sampler size of 1 in. with the bag on the inlet side of the suction device, and for almost any size with the bag on the discharge side. It is equally suitable for pulverized-fuel and stoker-fired installations. The chief disadvantage of cloth bags is their short life which often causes failures in operation, especially at high load.

Cyclone Separator. Constant resistance for a given gas flow, lack of limitation in size, and ease of removing dust sample are points that make the cyclone separator very desirable. The only drawback to its use is its efficiency of separation. Most investigators have considered a filter necessary on the discharge of the cyclone. Stern (1) developed a cyclone which, for a limited range of sampling rates, obtained nearly 100 per cent

[4] For the purpose of this paper "dust concentration" is defined as the weight of dust per unit weight of gas.

separation. For different duct velocities, the size of sampler mouth was changed to keep the rate of gas sampling within the required limits. As a check on the efficiency of the cyclone he recommends the use of an electric precipitator in the discharge line. Figs. 5 and 6 show methods used by other investigators for combining a cyclone and filter. These combinations retain most of the advantages of the cyclone without having to change the sampler tips to assure complete separation.

Alundum Filter. If the gas temperature is above 350 F or if the gas is quite moist, alundum filters have been used to replace



(a) (b)

Fig. 6 Cyclone Separator With Internal Filter for Securing Complete Removal of Dust

(*a* The filter consists of a sheet of filter paper backed up with a metal screen, both of which are clamped between the cover and the body of the separator. See paper (3) by Zimmermann; *b*, A similar design used by Rosin and Rammler (12) which has several sheets of filter paper in parallel to reduce the resistance to gas flow.)

paper thimbles. In some cases the alundum filter is made the same size and shape as the paper thimbles so that the two are interchangeable (see Fig. 4*c*). The high resistance of alundum filters is a serious handicap to their use.

Metal-Screen Filter. As a substitute for cloth bags when the temperature is above 300 F, monel-metal screens of 100 mesh have been used (7). For tests on stoker-fired installations, the openings in the screen are quickly covered, thereby preventing further loss of small-size particles. The tests must be of such duration that the initial loss of small particles will be negligible. Like the alundum filter, the resistance of metal-screen filters is high, especially after the test run has been in progress for some time. If the rate of collection is high, the test run must be interrupted several times to brush the dust from the screens.

Glass-Wool and Schott Glass Filters. These two types of filter have been used mostly for laboratory experiments, although Zimmermann (3) reports their use on field tests. If the dust sample is desired for size analysis or combustible content, the separation of the dust from the glass wool presents a problem. The high resistance of the Schott glass filter is the main objection to its use.

Water-Bubbling Bottle. Separation of dust from the gas by bubbling the gas through water is a method that has been resorted to when the gas contained too much moisture to permit the use of any of the filter methods. It has the serious disadvantage that a large quantity of water must be separated from the dust by filtration and then evaporation.

General Considerations

Classifying dust samplers according to the means used to separate the dust has caused undue emphasis to be placed upon this function of the sampler, when emphasizing the sampling procedure is much more important. Efficient separation can be obtained with all of the separating devices. The choice between them should be governed largely by the kind of test to be made and the operating conditions to be encountered.

The most likely source of error in flue-dust measuring is due to faulty spotting of the samplers in the cross section of the gas passage. At best, a sampler can be expected to indicate the dust concentration only at the points where it is spotted. With a variation in dust concentration as great as 10 to 1, which is not uncommon even in long straight ducts, the spotting of the samplers is a potential source of error. Samples must be taken from at least 12 points to obtain reasonably reliable results. The samples can be obtained either by traversing with one or more samplers or by operating separate samplers at each point.

All samplers require considerable attention both in preparation for test and throughout the test period. Simon (10), however, reports the development of a recording dust-concentration meter, but whether this instrument would be satisfactory for test purposes is questionable.

To the author's knowledge, only one flue-dust sampler is on the market, a vacuum-cleaner type manufactered by Hudson H. Bubar.[5] Other types described therein were built specially.

Pease Anthony Gas Scrubbers

By M. D. ENGLE,[1] BOSTON, MASS.

IN THE Kneeland Street boiler plant of The Edison Electric Illuminating Company of Boston, two 250,000 lb per hr and one 350,000 lb per hr pulverized-coal-fired boilers are in-

---

[5] 15 Park Row, New York City.

[1] Superintendent, station engineering department, The Edison Electric Illuminating Company of Boston. Mem. A.S.M.E. Mr. Engle received the degree of B.S. in engineering from the University of Michigan in 1918 and, until 1922, was associated with the Consolidated Gas, Electric Light & Power Co., Baltimore, Md., first as an assistant construction inspector on an addition to its Westport central station and then as assistant to the electrical engineer. From

stalled for supplying steam to the district heating system in downtown Boston. Each boiler is equipped with two Pease Anthony gas scrubbers, manufactured by the B. F. Sturtevant Company, for removing the solid matter from the flue gases before they are discharged to the atmosphere.

Details of Construction

As can be seen from Fig. 1, these scrubbers consist of a vertical, cylindrical shell with a tangential gas inlet at the bottom and a central gas outlet, with antispin vanes, at the top. In the center of the scrubber, a vertical spray manifold is located which supplies the scrubbing water through approximately 90 $^3/_{16}$-in. nonclogging nozzles.

The steel shells are lined with plastic stack lining and acidproof brick set in acidproof mortar. The central spray-nozzle manifolds are made of Haveg, and the nozzles are made of hardened volcanic lava. Each nozzle handles about 1.75 gpm at 35 lb pressure. The scrubber drain lines are of rubber-lined steel pipe with a stoneware lining at the outlet from the scrubber to resist the erosive action of the water and solid matter leaving

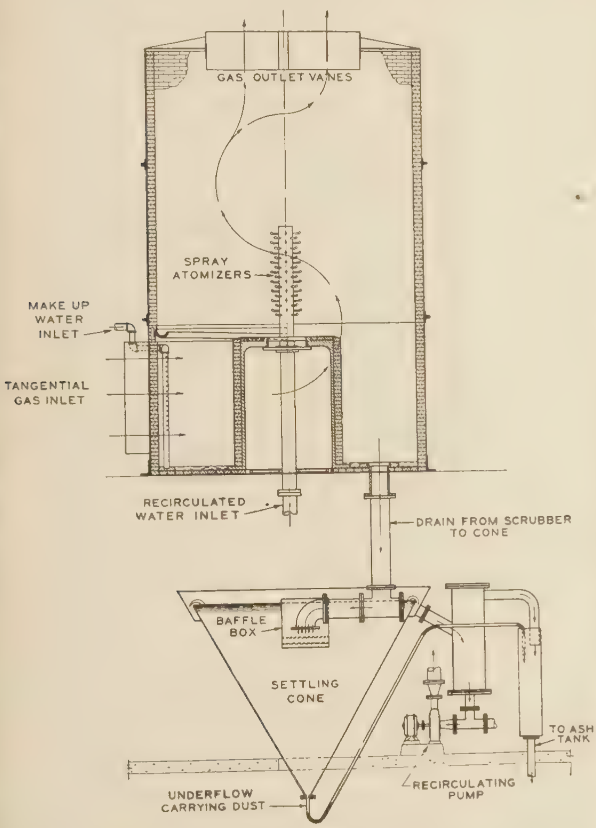

Fig. 1 Section Through Pease Anthony Gas Scrubber Showing Details of Construction and Arrangement

the scrubber. They discharge into a Callow cone for removing the greater part of the solids before the water is recirculated to the scrubber spray nozzles.

The steel Callow cones have 60 deg angles and are protected against corrosion by a rubber latex paint known as Sealvulc. The water enters at the center through a baffle box and flows outward and over the edge into a collecting trough and then passes to the recirculating pump. The solids with about 10 per cent of the water, are removed at the bottom and drain through rubber-lined steel or stoneware pipe to settling tanks.

The recirculating pump is rubber-lined and has a rubber-covered impeller. One pump recirculates the water to the two scrubbers serving one boiler.

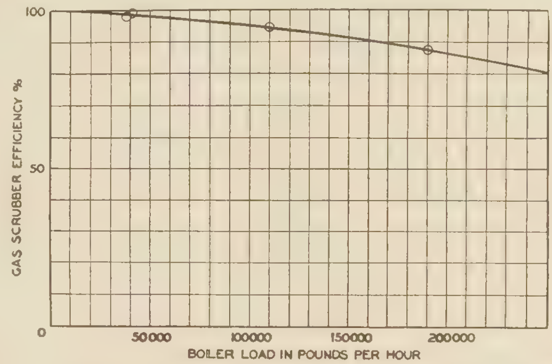

Fig. 2 Efficiency Curve Obtained From a Test of Two Scrubbers Serving a 250,000 Lb per Hr Boiler

The duct work, fans, and flues to the chimneys are sandblasted and painted with three coats of General Electric bakelite varnish No. 428, which is baked according to a schedule to give the greatest toughness and corrosion resistance.

Sufficient hot air, from the air-heater outlet, is discharged into the induced-draft fan inlets to reduce the relative humidity of the gas to approximately 50 per cent.

Operation Methods

In operation, the gas enters near the bottom and is given a violent spin by the tangential inlet. Scrubbing water enters through the many nozzles in the central manifold and is broken up into a very fine spray. The gas is saturated by the spray water, the solid particles are wetted and their weight increased, and both the solid matter and excess water are separated from the gas by the centrifugal force of the gas spin.

The gas flows upward and out through the central opening at the top, while the scrubbing water flows through the gas stream to the side walls of the scrubber. The water and solid matter drain down the side walls to the bottom of the scrubber and keep the side walls and bottom continuously wet and flushed off. The spinning gas scrubs the wet side walls continuously and aids materially in the scrubbing of the gas.

The gas-pressure loss through the scrubbers is approximately $1^1/_2$ in. of water at full load.

These are, so far as known, the only flue-gas scrubbers in this country using recirculated scrubbing water. At this plant, tidewater is not available, and recirculation is an economic necessity. The waste water in the boiler plant, such as boiler blowdown and backwash and rinse water from the zeolite softeners, is used as make-up water for the scrubbers.

The recirculating pumps handle from 1.5 to 2.0 gpm per 1000 cfm of gas scrubbed at full load. Since the quantity of scrubbing water is maintained constant, the water-to-gas ratio is much higher at light loads, which probably accounts for the higher efficiency of collection obtained at less than full load.

The temperature of the recirculated scrubbing water varies from approximately 110 to 140 F, with temperatures for the gas entering the scrubber varying from 350 to 500 F. The acidity

1922 to 1925, he was assistant to the chief mechanical engineer with McClellan & Junkersfield, Inc., severing that connection to become assistant to superintendent of the station engineering department with The Edison Electric Illuminating Company of Boston. In 1935, he assumed the duties of his present position.

of the scrubbing water, with 0.50 to 0.75 per cent of sulphur in the coal, varies from 0.05 to 0.30 per cent of acid calculated as sulphuric acid. While most of the acid in the water is sulphuric, traces of hydrochloric, nitric, and sulphurous acids have been found. The pH of the scrubbing water varies from 3.00 to 1.75.

This water is very corrosive, and very few metals or alloys that will withstand its corrosive action are available. As will be noticed, nonmetallic materials are used exclusively in the construction of these scrubbers wherever a possibility of scrubbing water being present exists. Four of these scrubbers have been in operation 6 years and two of them for 5 years. We feel that the major design and operation problems have been solved, and that the scrubbers are now developed to a point where they can be installed with the confidence that they will operate satisfactorily for the purpose intended.

A careful test has been conducted on the pair of scrubbers serving one of the 250,000 lb per hr boilers. Although any test on dust-catching apparatus is open to question, we believe that the results of this test are reliable. Fig. 2 shows the efficiency curve obtained from this test. During the last two runs, the dust content of the entering gas was very low, 0.600 to 0.276 g per cu ft. Had the content been higher, the efficiency of collection would also have been better.

Scrubbers in Good Condition After 6 Years Service

The steel shells and their acidproof-brick linings have been free from trouble and, after 6 years of operation, appear to be in as good condition as the day that they were installed. Cast-iron spray-nozzle manifolds, 1 in. thick, were used at first and had a life of about one year. Now, manifolds of Haveg are being used, and some of these have been in service two years. This material appears to have a long life if the scrubbers are not operated without water but does have a somewhat lower temperature resistance than would be desirable. Nozzles of an acid-resisting alloy were used at first and failed within less than 6 months. Molded bakelite nozzles were tried and failed within 10 days. Nozzles of hardened volcanic lava have been in service 2 years and appear to have a life of three or more years.

To guard against high temperatures in the scrubbers, a set of emergency spray-nozzles has been installed in the scrubber inlet and is supplied with water from the scrubber make-up pumps. An automatic valve admits water to these nozzles whenever the pressure delivered by the recirculating pump falls below a safe value.

Where rubber-lined pipe is used, a hard-rubber lining has been found to resist the corrosive action of the scrubbing water best. Soft-rubber linings best resist the erosive action of the solids carried in suspension in the scrubbing water. Some semi-hard-rubber-lined drain lines have been in continuous service for 6 years without failure, while some soft rubber-lined pipes subjected to turbulent flow have failed completely in 3 years. When properly installed, chemical-stoneware drain lines seem to be well suited for handling the scrubber water and entrained solids. We have not had a long enough experience to secure data on the life of this material but intend to use it in the future.

The Sealvulc latex paint stands up on the Callow cones satisfactorily for 1 year. The surface is then cleaned and patched, and two additional coats applied with a paint spray gun. This treatment is relatively inexpensive and is satisfactory.

The rubber-lined pumps with rubber-covered impellers were manufactured by the Allis Chalmers Mfg. Company, and the rubber work was done by the Manhattan Rubber Company. They operate at a head of approximately 50 lb and have performed very satisfactorily as recirculating pumps.

By sandblasting and repainting the ducts on the discharge of the scrubbers and the inside and rotor of the induced-draft fans annually, they apparently will last for many years. After 6 years of operation, the fans are almost as good as new, but, if the fans and rotors are not repainted annually, serious corrosion takes place.

Dehydration of Solid Matter

Another problem, which has been difficult to solve, has been the dehydration of the solid matter after it has been caught by the scrubber. The solids scrubbed from the boiler-flue gases are so small in size that they settle very slowly and do not, by settlement, form a compact mass which can be handled by ordinary means. The permeability of the solids is so low that removing sufficient water from the voids to give a semidry cake which can be easily handled is very difficult. We have a device for this purpose in service which seems to offer a satisfactory answer to the problem.

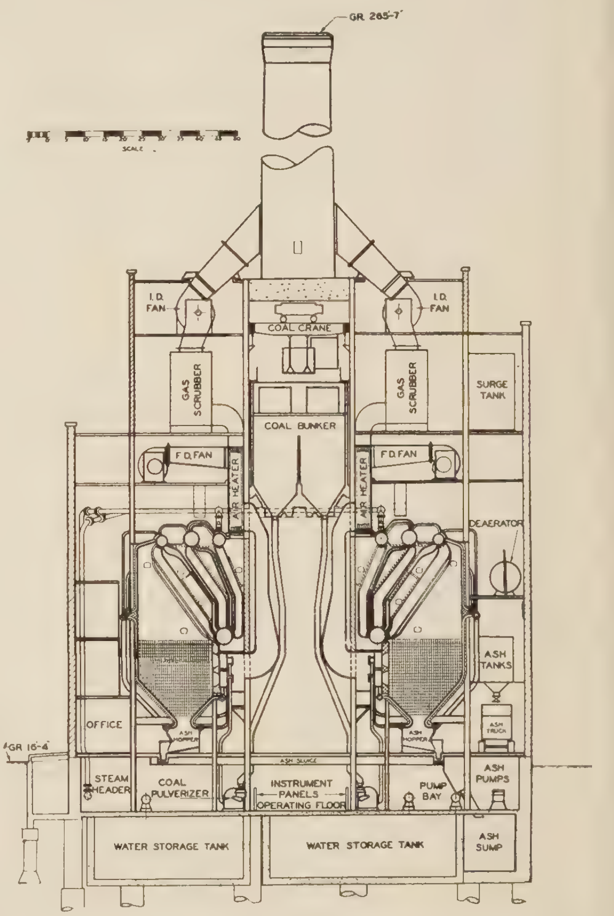

Fig. 3 Cross-Section of the Kneeland Street Station Showing Location of the Gas Scrubbers With Relation to Rest of the Equipment

Fig. 3 shows how these scrubbers have been fitted into the Kneeland Street Station. As will be seen, they are located between the air-heater outlet and the induced-draft inlet.

Many problems remain to be solved before the perfect gas scrubber is developed. In spite of the lack of fundamental research, however, many satisfactory gas-scrubber installations have been made and are in everyday operation. Many of us believe that the gas scrubber is the most satisfactory apparatus available for removing solid matter from boiler-flue gases.

Hell Gate Spray Zone Gas Washer

By J. J. Grob,[1] New York, N. Y.

FLY ASH is difficult to remove from flue gases because of the large percentage of extreme fines. A substantial percentage of coarse grit may also be present at times. Many types of dust eliminator which proved to be fairly successful in dealing with stoker cinder have failed to provide satisfactory elimination of fly ash in connection with pulverized-coal boilers. Several types of spray eliminator for powdered-coal boilers have demonstrated that exceedingly high dust-eliminating efficiency is made possible by washing the gases with finely divided water sprays and further indicated that the performance is not selective as to the size of dust particles. In the present spray-eliminator design, an important saving in water requirements has been made possible by combining the effects of inertia, downward flow, change of direction, and change of velocity together with the agglomerating action of the water sprays.

The Hell Gate spray zone fly-ash eliminator is a comparatively simple and compact arrangement for the application of sprays in the removal of fly ash from flue gases. It consists essentially of a reversing chamber with a spray header carrying a row of spray nozzles near the point of gas reversal, as shown in Fig. 1.

The entrance chamber is positioned so that the gas flow is directed downward and the velocity is increased as the gas approaches the spray zone. After it passes through the spray zone, the outlet passage is enlarged so that the gas can leave the spray zone at a reduced velocity as it turns abruptly upward. In its upward path, the gas is directed through corrugated or alternately spaced dehydrating plates to arrest entrained moisture and uncaught dust agglomerates. This arrangement is illustrated in Fig. 2. Jetting nozzles are provided to remove periodically accumulations of lodged fly ash from the dehydrating plates, generally about two to three times per day.

Three of these eliminators are now in service at the Hell Gate Station serving boilers Nos. 81, 82, and 83, each having a capacity of 400,000 lb of steam per hour. Due to crowded conditions in the eighth-boiler row, no other type of fly-ash eliminator, which might have been considered, could be accommodated in the limited space available. One hundred and fifty gallons of sea water per minute is utilized in the spray zone of each eliminator. Sea water is employed in the spray zone as this is the cheapest source of water supply, involving relatively small pumping charges.

Many exhaustive tests were conducted on No. 83 eliminator which was the first installed. Fig. 3 and Table 1 indicate a general dust-elimination efficiency of 97 per cent and some details of test results. Methods of test followed experience gained with tests of various experimental catchers at Sherman Creek Station over a period of years. Multiple dust-sampling traverses were conducted at velocities corresponding to the gas velocity at the

[1] Engineer of Tests, New York Edison Company, Inc. Mem. A.S.M.E. Mr. Grob was associated with the Electrical Testing Laboratories, New York, N. Y., from 1911 to 1914, when he accepted a position at the main power station of the Hudson & Manhattan Railroad, Jersey City, N. J., where he remained until 1920. During this period, he was a student at Pratt Institute, Brooklyn, N. Y., in the electrical course, being graduated in 1917, and continued his studies at Columbia University by taking special courses and later at Polytechnic Institute of Brooklyn, receiving the degree of M.E. in 1926. After leaving the Hudson & Manhattan, he was employed by the Dwight P. Robinson Co., as designer and checker on the mechanical and electrical features of the Colfax power station for the Duquesne Light Company, Pittsburgh, Pa., for a year. In 1921, he was appointed to his present position with the New York Edison Company, Inc.

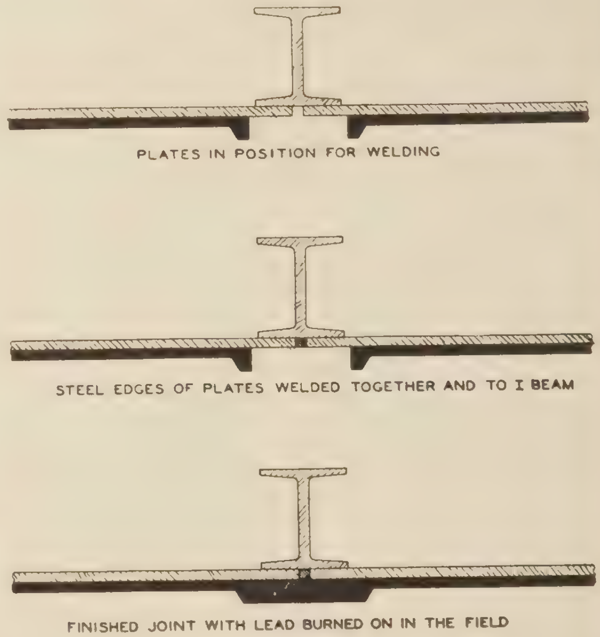

FIG. 4 METHOD OF PROTECTING WELDED SEAMS IN HOMOGENEOUS LEAD-COVERED PLATES

position of sampling. The gas samples were drawn through filter bags and then through metering orifices.

Many kinds of material were exposed to the gas and salt water to determine their suitability for corrosion resistance. In the recent installations on boilers Nos. 81 and 82 lead-lined steel plates are used for the walls exposed to water. The lead is $^1/_4$ in. thick and is bonded to the steel by the homogeneous process. Fig. 4 indicates how the welded joints are built up with lead and Fig. 5 shows a sample of lead-clad plate. While planning for corrosion and erosion resistance was necessary, this problem has been reduced to the minimum for wet catchers because of the small quantity of spray water, use of dehydrating plates, and avoidance of gas supersaturation.

The bottom pan of No. 83 eliminator consists of $^3/_4$-in. steel plates, bare except for occasional coats of emulsified asphalt. This unit has been in service over 5 years, and the only attention that the pan has required has been the welding over of rivet heads which had been worn down by the abrasive action of grit in motion. If future experience indicates any need of further protection, the pan could be lined with brick or cement. The most severe corrosion service is experienced on the walls of the container just under the dehydrating plates where acid concentrations may build up. This situation has been met by using homogeneously bonded lead-clad plates. Since the operating availability of the eliminator greatly exceeds the operating availability of the boiler, no by-passes have been considered necessary on the eliminators installed at Hell Gate.

Operating attention is simple, involving the backwashing of twin strainers on the water supply and jetting the dehydrating plates about once every 8 hours. Inspection of the nozzles takes place on a Sunday outage. Fouling of nozzles is infrequent. In the course of a year and a half or two, when the dehydrating plates begin to wear thin, any convenient boiler outage involving two or three days is utilized to replace the plates. As the transite

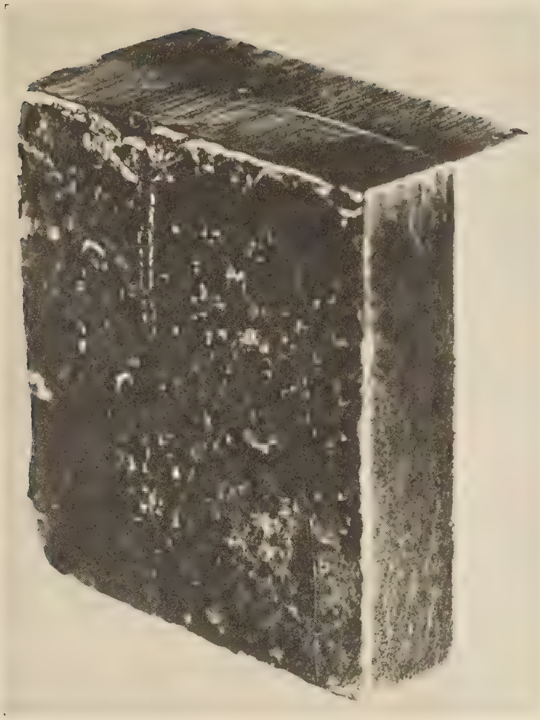

FIG. 5 SAMPLE OF 1/4-IN. LEAD PLATE BONDED TO A STEEL PLATE OF EQUAL THICKNESS

dehydrating plates are comparatively cheap, considerable latitude in the selection of time for replacement is provided.

Cindervane Fan

BY H. F. HAGEN,[1] BOSTON, MASS.

THE CINDERVANE was, so far as I know, the first successful device to utilize changes in direction of flow that occur in a fan impeller to separate dust from flue gases. The possibilities of such action were emphasized in 1916 by W. S. Finlay who wrote a complete and seemingly serious specification calling for cinder-eliminating fans for induced draft at the 59th Street Station of the Interboro Rapid Transit Company. In an interview with a rather bewildered fan engineer who had never heard of any such apparatus, Mr. Finlay explained that, while he knew nothing of the kind was on the market, he thought there should be and he wanted us all to consider the problem.

About a year later, our research department invited Mr. Finlay to witness a test on a model 24-in. fan. The results of the test were satisfactory and two 12-ft fans were ordered. The impeller design was based on the steel-plate paddle wheel and provided outwardly inclined channel irons attached to the blades to convey the cinders to collecting chambers in the sides of the casing.

The fans were installed and put in operation in 1918 and gave a satisfactory performance. They handled the required duty at a fair efficiency and more than met the guaranteed cinder-recovery efficiency. Each fan actually threw down 250 lb of cinders per hour, when the boilers were operating at high load, which in those days, was 250 per cent of the rating.

Mr. Finlay offered us an order for 14 more units to equip the station completely but required a delivery that we could not meet in view of the business already in our shop. I have always felt that, if we could have filled that order, the history of the Cindervane would have been different. That installation would, in all probability, have resulted in a large business and encouraged research and commercial activity. As it was, the device achieved some notable successes and a slowly increasing business, about a quarter of a million dollars in the next 5 years. The advent of pulverized coal and the large increase in induced-draft pressures made that specific design obsolete.

The Cindervane was a successful apparatus and may serve to illustrate the advantages and disadvantages of this type of cinder eliminator. The former are

(1) Draft loss for the cinder elimination is small. The required modification of the fan blades reduces the fan efficiency less than 5 per cent.
(2) Only a small amount of additional space is required.

The disadvantages are more numerous; they are

(1) The blade becomes a limiting factor from a standpoint of strength
(2) Abrasion is rapid
(3) Dust-separating efficiency is low with micronic sizes.
(4) Passages for the separated dust are necessarily small and some trouble from clogging may be expected.

However, the writer's laboratory experience has shown that (3) applies to all attempts at dry centrifugal separation in limited space, so that this objection is generic rather than specific and typical.

In view of modern trends in power-plant design, further development of the dust-separating fan impeller do not appear commercially attractive.

[1] Manager of research, B. F. Sturtevant Company. After being graduated from Stevens Institute of Technology in 1907 with the degree of M.E., Mr. Hagen worked for approximately 18 months as piece checker in the Erie Railroad shops at Cleveland, Ohio. For about the same length of time, he was an electrical and construction engineer with Walter Kidde, New York, N. Y., and in 1910, accepted the position of engineer of design and tests with the Green Fuel Economizer Company, Beacon, N. Y. He severed this connection to accept his present position in 1916.

Cleaning Combustion Gases by Electrical Precipitation

BY C. W. HEDBERG,[1] BOUND BROOK, N. J.

COTTRELL electrical precipitation processes are an established means of fly-ash and cinder elimination. Their principal application, in this field, is in those cases where removal of from 90 to 98 per cent of the total suspended material carried by the gases is necessary or desirable. At the end of 1935, 19 installations were handling gases from 61 boilers with a normal steam output of 19,700,000 lb per hr in the last year, users have purchased 12 installations for 25 boilers with a combined steam output of 6,800,000 lb per hr.

THREE PRECIPITATOR TYPES AVAILABLE

The composition-plate precipitator continues to be preferred, six of the twelve installations purchased in 1936 being of this

[1] Chief of technical and development department, Research Corporation. Mr. Hedberg's connection with electrical precipitation dates back to 1916 when he first joined the Research Corporation, and this connection has continued except for a three-year period spent in the research department of the New Jersey Zinc Company. He is a graduate of Worcester Polytechnic Institute, a member of the American Institute of Chemical Engineers, and author of several papers on the application of electrical precipitation.

type. Because of weight and available-space considerations, two additional types, have been added, one embodying a rod-curtain collecting electrode and the other a vertical-flow pocket electrode. Five of the former and one of the latter have been built in 1936.

Construction and operation of the composition-plate precipitator is generally known and requires no extensive description. It is built in two or more separate banks of electrodes in series, each section consisting of as many as 15 parallel ducts formed by large concrete slabs that act as grounded collecting electrodes. Discharge electrodes hang centrally in the ducts and, when energized, charge the particles suspended in the gases and remove them from the gas stream to the collecting electrodes. When the deposit has reached a certain depth, a large portion loosens from the collecting electrode and drops into the hopper as heavy agglomerate, and the remainder is removed by a scraping system at regular intervals.

In general arrangement, the rod-curtain precipitator is markedly similar to the concrete-plate unit, the principal difference being in the type of collecting electrode and the method of dust removal. Instead of large concrete plates, the collecting electrodes are curtains consisting of a pipe framework in which are threaded a number of vertical parallel rods. These curtains are hung from the top so that they can be moved in their plane and forcibly returned against an anvil at the bottom, thereby vibrating the curtain throughout and dislodging the accumulated dust which falls into the hoppers. The rapping is carried out continuously or at necessary intervals through a mechanism actuated by solenoids, the whole operation being automatically controlled. For equal gas volumes, the height and width of the rod-curtain precipitator are essentially the same as dimensions for the concrete-plate type. The former is $3^1/_2$ ft shorter and weighs approximately 45 per cent less than the latter.

The vertical-flow pocket-electrode precipitator is particularly adapted to removal of cinders and soot from the combustion gases of stoker-fired boilers, and this has been its principal application. On fly ash from pulverized coal, it is just as effective as the two other types but is somewhat more expensive, and this fact limits its use to those cases where it can be furnished in economic-size units and fitted into existing arrangements to effect substantial savings in costs of supports and flue connections.

This precipitator differs from the other two in that the gases to be cleaned enter through the hopper, rise vertically through the ducts and leave through a breeching connected into an existing stack or through a stub stack which is carried on the precipitator itself.

The ducts are formed by parallel electrodes built up of six individual sections or hung from a top member. Pockets are formed in the sides of these boxes which provide louver-like openings into the interior, and, when the electrodes are vibrated by a mechanism provided for this purpose, the dust deposited on the electrode surface is loosened and falls through the openings into the box and is carried down into the hopper in a quiescent zone where the possibility of its becoming resuspended in the moving gases is little, if any. The arrangement of discharge electrodes and supports is, in general, identical with that in the other types described.

While the height is greater, it occupies less floor space than the other two types. In weight, it compares favorably with the rod-curtain precipitator.

Methods of Energizing

The usual method of energizing precipitators by rectified, full-wave current at a high potential is well known, and, when so energized, the power consumption is approximately 3 kwhr per 1,000,000 cu ft of gas cleaned. In the last year, mechanical rectifiers have been designed for a circuit employing half wave instead of full wave, and this promises to be a very definite advance in the art.

One half-wave mechanical set will do the work of two full-wave electrical sets with approximately half the power consumption and no measurable loss in efficiency. Electrical operation is smoother with less arcing in the precipitator, which has substantially decreased the scraper-chain and discharge-electrode breakage that has occurred on some installations as a result of excessive arcing.

General Arrangement of Precipitators

Most of the early precipitators for this service were located on the power-house roof between the induced-draft fan and the stack. In later years, and particularly on present new construction, most of them are located after the preheaters and before the induced-draft fans, and, while some continue to be located on the roof, a number are wholly within the buildings.

Not only does the location ahead of the fans markedly decrease fan-blade errosion, but it also simplifies the problem of distributing the gases over the cross-section of the precipitator. These desirable results are due to the fact that the gases leaving a preheater are usually moving through a much wider flue and at lower velocities than at the exit of the fan.

Operating Results

Builder's tests, employing the Brady method to determine average concentration of suspended matter in the gases throughout the cross-section of the inlet and outlet flues, have been conducted on most of the concrete-plate installations to secure performance data. These have shown removals consistently in excess of 90 per cent at normal ratings and, as these ratings are exceeded, the efficiency shows a drop of about 5 per cent at 125 per cent of rating and 12 per cent at 150 per cent. Generally, the percentage efficiency is slightly less on material coarser than 200 mesh than on finer, but, since the former usually comprises less than 10 per cent and in some cases as little as 5 per cent of the total suspended material, this characteristic is of minor importance.

As rod-curtain precipitators have been built only within the last year, operating results are now available on only one precipitator of this type. This showed an average efficiency of 94 per cent at rated volume and 90.3 per cent during flue-blowing periods.

With the pocket-electrode type of precipitator, efficiencies in excess of 90 per cent have been obtained in removing cinder, ash, and soot from combustion gases from stoker-fired boilers. The result has been practically invisible stack exits.

Static-pressure drop through a precipitator amounts to approximately 0.2 in. of water at normal ratings. Hence, no appreciable interference with draft conditions occurs.

Maintenance costs on the units have been very low. A recent survey made by a disinterested party indicates that they will not exceed 1 cent per ton of coal fired.

Increasing attention is being given to the inclusion of means for eliminating the discharge of cinders and fly ash from boiler stacks, particularly where new construction is involved. Furthermore, guarantees of 95 per cent and higher have already been specified on two installations so that the trend may be toward even cleaner exits. To the present time, electrical precipitators have played an important part in solving the problem, and continuous efforts are being put forth to increase their utility in this field.

Thermix Recirculator and Controlled Multicyclone

By L. C. WHITON, JR.,[1] PORT CHESTER, N. Y.

ORDINARILY the apparatus under discussion is considered as dust collectors. They might be more appropriately called dust losers because we are not interested in the material collected. As a matter of fact, many letters have been received from plants using our dust collectors, telling what a nuisance it is to collect so much dust. We are interested in the quantity and kind of dust that is lost.

At present, if between 8 and 10 per cent of the fly ash in a pulverized-fuel installation is allowed to escape, that is generally considered to be satisfactory operation. Our attention should, therefore, be concentrated upon what type of dust escapes, as well as how much is collected. The quality from a nuisance standpoint is fully as important as the quantity.

Fine Dust Constitutes the Minimum Nuisance

We recently made a test on fly ash containing 22 per cent of combustible from a pulverized-fuel installation. The average dust escaping the "thermix multicyclone," which amounted to 8.2 per cent of the total, was 11 microns with no particle coarser than 19 microns. The analysis of the combustible in the escaping dust was 15 per cent. This dust, according to Stokes' law, would travel approximately 8 miles in a 5-mile wind from the average stack. This was then compared with dust which averages 200 mesh and coarser. The combustible content in this case was 46.4 per cent against the average 22 per cent in the ash from the boiler. Even though all of this dust were 200 mesh, Stokes' law indicates that it would drop to the ground from the same height in less than 1000 ft of travel. Considering the quality of the material lost as the important point, fine dust constitutes the minimum from the nuisance standpoint. We feel that this point has been neglected in the past, but that, in the future, qualitative as well as quantitative dust collection will be borne in mind.

Of the two types of dust collector manufactured by the Prat-Daniel Corporation, the first is the "thermix recirculator," and the second is the "thermix controlled multicyclone." Briefly described, the recirculator is of the skimmer type and was the first of the type introduced in this country. The original installation was made in 1928 after 250 operating plants abroad were so equipped.

Skimmer-Type Dust Collectors

Dust collectors of the skimmer type have three essential parts. One is a circular passage in which the dust is concentrated toward the periphery, the second is the cutoff or skimmer opening along the periphery for withdrawing this dust plus a small percentage of gas, and the third is a cyclone for precipitating the concentrated dust in the gas with which it is withdrawn.

Since a certain amount of resistance must be overcome, a fan of some type is required and may be the induced-draft fan itself, or may be incorporated with the apparatus, as in the recirculator which also frequently acts as the induced-draft fan. The position of the fan wheel, in relation to the primary circular passage, is of considerable importance. If the fan is placed *before* the primary concentrator for the dust, the greatest suction in the entire system will, of course, be at the fan inlet. Any dust that escapes the secondary cyclone can, therefore, be brought back to the fan inlet and again passed through the primary concentrator.

If the fan is placed *beyond* the primary concentrator, the contrary will be true and without an auxiliary fan, the dust cannot be sent through the primary concentrator a second time. A more complete discussion of these two points, which have a serious influence on the degree of collection, is contained in an article[2] that was published recently.

The recirculator has the fan placed before the primary concentrator, thus allowing natural and normal recirculation from the cyclone to the primary concentrator a second time. To take some simple figures, assume that 90 per cent of the dust is concentrated in the primary passage and passed to a cyclone which is 80 per cent efficient. Without recirculation, the overall efficiency would be 0.8×0.9, or 0.72. With recirculation, according to the formula in the article mentioned, the collection would be 87.8 per cent. These percentages of concentration in the primary concentrator and collection in the cyclone can be varied in any desired combination but the fact is still evident that, with recirculation, a higher collection will result than without it, although not necessarily precisely the calculated theorectical amount.

The advantage of removing the dust before it reaches the fan blades would be of importance were it not that, in the recirculator where the fan is placed before the concentrator, cast wearing surfaces are placed on the fan blades, even with high-speed fans. These blades can be replaced without removing the wheel or the necessity for rebalancing when new blades have been installed. Approximately 50 per cent of the recirculators in the United States operate upon pulverized fuel and are doing entirely satisfactory jobs for the users, and the other 50 per cent operate upon stoker firing.

Utilization of Centrifugal Force in Dust Collection

However, to obtain the highest degree of collection with pulverized fuel which is frequently required in the central-station field, with an assurance that less than 10 per cent will escape, we generally advocate the use of the thermix controlled multicyclone. Basically, the formula for centrifugal force is mV^2/r, and the smaller the radius r is, the greater will be the centrifugal force. Furthermore, this force varies as the square of the velocity V of the gas.

To utilize this principle, the multicyclone is composed of a series of cast-iron cyclones approximately 2 ft in diameter arranged in parallel to insure high collection. Tests have shown that a 1-ft cyclone will increase collection approximately 2 per cent, but a 3-ft cyclone decreases collection approximately 2 per cent, and, for all practical purposes, a 2-ft cyclone gives sufficiently high collection in a limited space. For example, the gas from a boiler developing 100,000 lb per hr of steam can be handled in a ground area of approximately 220 sq ft or 110 sq ft if double-decked.

Two methods are used to maintain a constant velocity at varying loads. These methods are necessary because, if the load drops to one half the maximum designed load, the velocity will be one half and the centrifugal force one quarter. One method used is to decrease the number of cyclones in the circuit proportionately to the decrease in load, thus maintaining the collection constant at all loads. The other method is to partly close the dampers by utilizing a damper that throws the dust to the outside edge of the cyclone, thus mechanically compensating for

[1] President, Prat-Daniel Corporation. Mr. Whiton was graduated from Sheffield, Yale University, in 1912 and received a master's degree at Columbia University in 1913. His early experience was in connection with engineering problems for the recovery of waste products in the by-product coke-oven industry and later in the oil industry. He has been president of the Prat-Daniel Corporation since its inception in 1924. He is the author of numerous papers on the subject of induced-draft fans, heat-recovery devices, and particularly on dust collection from flue gases, in which he has specialized for the last ten years, holding a number of patents in that connection.

[2] "Recirculation in Skimmer Type Dust Collectors," by L. C. Whiton, Jr., *Power Plant Engineering*, vol. 40, 1936, p. 705.

lower centrifugal force due to lower velocity within the cyclone.

It would be impossible in this short paper to give fully results of the many tests which have been run to determine the efficiency of the thermix multicyclone. A typical example, however, is a test run some time ago under the supervision of and checked by three central-station engineers, using pulverized-fuel dust which had run 80.25 per cent through a 325-mesh screen. The overall collection efficiency at 400 F was 91.8 per cent. When operated at 70 per cent of the load the collection increased to 93.8 per cent due to the method of control used with this system.

To summarize, the recirculator, which overcomes its own resistance because of its fan, or which may act as an induced-draft fan, is important as a dust collector because of the recirculation principle. The multicyclone is the best development, of which we know, from the standpoint of extremely high collection with mechanical collectors. Both systems allow the least obnoxious type of material to escape when our attention is directed to the quality as well as quantity of dust that escapes, rather than having our attention concentrated only on the dust collected.

Riley Flue-Gas Scrubber

By O. CRAIG,[1] WORCESTER, MASS.

REMOVAL of fly ash from the gases passing up the chimney as a result of combustion is accomplished in the Riley flue-gas scrubber by causing the particles of ash to impinge on vertical carbon plates as the gas travels in staggered paths between the elements of the device. The surface of these plates which is exposed to the passage of the gas is kept wet, and this moisture causes the particles to adhere. The flow of water over the surface of the plates removes the accumulation of particles.

The construction of the scrubber is shown in Fig. 2. A series of flat carbon elements or plates, *A*, are arranged vertically in staggered formation between two horizontal tanks and two vertical side walls constituting a tunnel. Top tank *B* is a shallow, open reservoir into which water is fed at a constant rate through a pipe manifold *C*. Water, from the top of the tank, flows by gravity through metering orifices *D* into distributor boxes *E*. Elements are built in sections, each tied together rigidly with two lead-coated steel rods that are completely embedded in the carbon, and stand on the flat floor of the bottom tank *f*. The upper ends of the elements are guided by ribs *g* cast on the underside of the top tank. Elements are inserted through access doors *h* provided in the side walls of the housing. Five orifices *i* in each distributor discharge water over both surfaces of each element. Three orifices feed the surface facing the gas flow and two orifices feed the opposite side.

[1] Manager, engineering department, Riley Stoker Corporation. Mem. A.S.M.E. Mr. Craig was graduated from the University of Illinois in 1909 with the degree of B.S. in mechanical engineering and spent seven of the next nine years in teaching mechanical engineering at University of Colorado, Vanderbilt University, University of Texas, and Iowa State College. He spent one year, 1911–1912, as an assistant engineer at the United States Forest Products Laboratory, Madison, Wis., and conducted a research on timber seasoning, and for a year, 1914–1915, held the position of combustion engineer in the chain-grate department of the Laclede-Christy Clay Products Company, St. Louis, Mo. In 1918–1919, as mechanical engineer with the Charles L. Pillsbury Company, Minneapolis, Minn., Mr. Craig had charge of the operation of all State power plants under the State Board of Control; and the following year, he was engaged in perfecting processes for the utilization of powdered coal for the McLaughlin Coal Reduction Company, Decatur, Ill., as its chief engineer. Since 1920, when he received the degree of M.E. from the University of Illinois, Mr. Craig has been associated with the Under-Feed Stoker Company of America, Detroit, Mich., and the Riley Stoker Corporation, Worcester, Mass., as research engineer until 1936, and, since then, in his present capacity.

The gases travel in staggered paths between the elements *A*. In making changes of direction, the solid particles are thrown out of the path of the gases against the wet plates. These particles adhere to the moisture on the wet plates and are carried down by the water into the lower tank *f*. Water and solid particles collected in the lower tank are discharged through a manifold *j*, into a disposal system.

Corrosive acids are formed by the combination of scrub water and certain elements in the gases. This requires the selection of materials for construction which resist this corrosive action. Sides and the bottom tank are made of steel and are completely lined with acidproof tile laid in acidproof cement. Top tanks are made of cast iron with proper protection on the underside against direct attack of the flue gases. Parts most susceptible to corrosion are vertical elements or plates. These are made of extruded carbon, and long use indicates practically no deterioration.

Dust-Removal Efficiency. Efficiency of recovery expressed in percentage of dust loading is plotted against percentage of scrubber capacity in Fig. 1. Maximum scrubber capacity is equivalent to maximum boiler capacity. Rated scrubber capacity is usually chosen to correspond to what might be considered as a normal load on the boiler. At rated capacity, the velocity of gases entering the scrubber is approximately 1000 fpm. From 85 to 100 per cent of rated scrubber capacity, recovery is 90 per cent or more of dust loading. At half the rated capacity, recovery drops to about 75 per cent of dust loading.

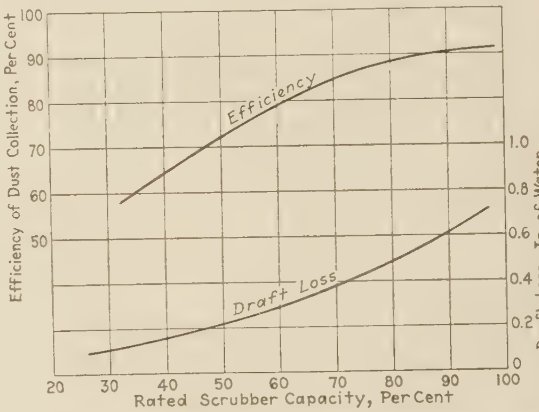

Fig. 1 Performance Curves Showing Dust-Removal Efficiency and Draft Loss With an Entering-Gas Velocity of 680 Fpm

Draft Loss Through Scrubber. The draft loss is also shown by a curve in Fig. 1. At rated capacity, this is approximately 0.8 in. of water and at half of rated capacity, approximately 0.2 in.

Drop in Flue-Gas Temperature. Due to contact with cold wash water, the temperature of gases leaving the scrubber is less than that at entering. Experience has shown that with water entering the scrubber, at 60 F, the drop in flue-gas temperature varies from 120 to 250 F, corresponding to inlet-gas temperatures of 350 to 600 F, respectively. Reduction in gas volume due to decreased gas temperature compensates for the draft loss through the scrubber, so that the same size of induced-draft fan is still suitable, and the power required for this fan remains practically the same.

Water Requirements. Standard practice is to supply water at the rate of $2^1/_2$ gal per 1000 cu ft of flue gas at the maximum scrubber rating and to maintain the water supply constant regardless of variations in load. This corresponds to approximately 6 lb of water for each pound of coal burned at maximum boiler capacity.

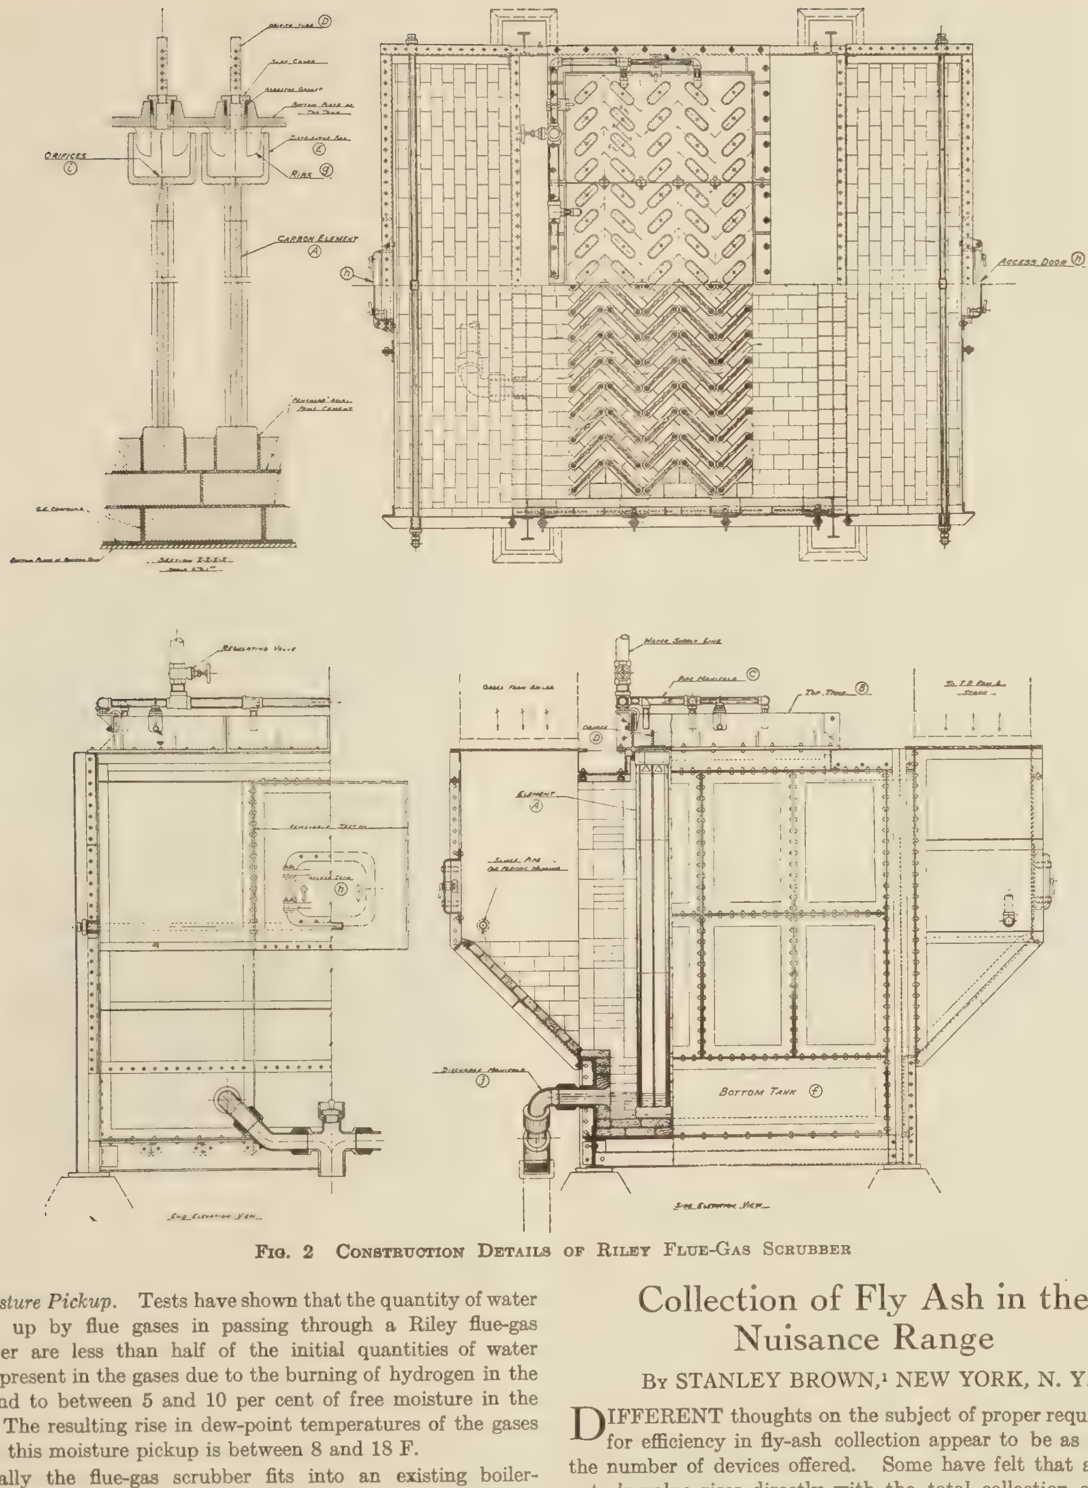

Fig. 2 Construction Details of Riley Flue-Gas Scrubber

Moisture Pickup. Tests have shown that the quantity of water picked up by flue gases in passing through a Riley flue-gas scrubber are less than half of the initial quantities of water vapor present in the gases due to the burning of hydrogen in the coal and to between 5 and 10 per cent of free moisture in the coal. The resulting rise in dew-point temperatures of the gases due to this moisture pickup is between 8 and 18 F.

Usually the flue-gas scrubber fits into an existing boiler-plant design readily. In one particular case, the scrubber is on the same floor as the induced-draft fan. The gases pass through the boiler, an air heater, then through the scrubber and into the induced-draft fan. The space which is occupied by the scrubber is approximately that occupied by the induced-draft fan.

Collection of Fly Ash in the Nuisance Range

By STANLEY BROWN,[1] NEW YORK, N. Y.

Different thoughts on the subject of proper requirements for efficiency in fly-ash collection appear to be as many as the number of devices offered. Some have felt that an eliminator's value rises directly with the total collection efficiency which it exhibits. However, according to a reasonable sizing

[1] Buell Engineering Co., Inc. Mr. Brown was graduated from the electrical-engineering course of Columbia University in 1902. He served for one year with the Cornell Iron Company on structural-steel work and for two years with Peet and Powers on electrical contracting. He was resident manager of the New York office of

acceptance as defining the lower end of the nuisance range, the following thought is of interest. An overall collection efficiency of 90 per cent might be secured by catching exactly 90 per cent of all particles of various sizes, while a device having an overall efficiency of 80 per cent might actually possess an average collection efficiency of 95 per cent throughout the nuisance range, and, if so, this would be preferred.

We do not have to turn many pages in the power-plant history to find a parallel with the present progress in fly-ash collection achievement. With the awakening of wisdom in "heat balance," strife raged through several years as to which plant could show the highest efficiency in British thermal units per kilowatthour. But it was soon evident that efficiency is of primary interest only when referred to the proper denominator, or shall we say when referred to the proper size of particles, which particles, in power development, are the dollars per 1000 kwhr.

Greater Size Consciousness Needed

So let us think together wisely. What is required?

If we consult our brothers on the Continent where there are many times the number of fly-ash eliminators that have been installed in the United States, we find the following reply: "In about May of this year, the imposed requirement for avoiding fly-ash nuisance was carefully refined to the specification that the collector must catch 90 per cent of all particles of 30-micron [1μ = 0.001 mm = 0.000039 in.] size, submesh 500, and larger."

In this regard, Dr. Otto Schoene, a professor at Charlottenburg University, who has had extremely broad experience in fly-ash study, states that if a fly-ash eliminator could accomplish a 90 per cent collection efficiency for all particles of 20-micron size and larger, the result would be beyond criticism.

Are we sufficiently "size conscious?" The smallest size of particle that is usually observed by unaided eyesight, with 12 ft-c of illumination, is approximately 35 microns (submesh 450).

Finely ground cosmetic powders of the "air-spun" variety, which are prepared in special micronizers, comprise particles having a size of about 27 microns (submesh 530).

Let us now give a moment to the consideration of falling time as related to particle size, and assume the moderate stack height of 150 ft with sufficient discharge velocity from the stack to carry the particles another 50 ft. Table 1 gives data on the falling time in still air from a height of 200 ft. In a separate column is indicated the distance that the particles of various size would travel before traversing the vertical distance of 200 ft when subjected to a breeze of 5 mph. Weather statistics report that, at a height of 200 ft from the ground, air motion of less than 5 mph is rare.

TABLE 1 TIME OF FALL AND DISTANCE TRAVELED BY VARIOUS SIZES OF PARTICLES

Sizing of fly-ash particles Microns	Submesh	Time to fall 200 ft in still air, hr	Travel (in 5-mph breeze) while falling 200 ft, miles
20	625	0.715	3.58
10	1250	2.40	12.00
5	2500	9.20	46.00
2	6250	85.60	428.00

A significant element within the term "nuisance" is the percentage of combustible in the fly-ash particles. Since this content greatly increases with the increase of particle size, the wisdom of attacking the "offenders" that are the most objectionable is apparent. If the dust has a value, catching it in terms of total-collection efficiency is worthy of consideration. Whereas, if the dust is merely annoyance, let us deal directly with the nuisance range.

the Weston Electrical Instrument Company for 11 years; and for 17 years was sales manager with Griscom-Russell Company. He also spent two years in miscellaneous research. He has been with the Buell Engineering Company for two years as director of the dust-collection division.

Design and Performance of Buell Eliminator

And now a few words on the Buell eliminator (van Tongeren system) which, according to the known performance of approximately 90 fly-ash installations, is offered to give proper battle against "fly-ash nuisance." Fig. 1 illustrates the compound type of dust eliminator, comprising a concentrating chamber and a cyclone. The total gas to be cleaned enters the chamber, the dust seeks a position adjacent to the volute casing, and is shaved off with between 10 and 15 per cent of the total gas for actual collection in the cyclone.

Fig. 2 again shows the compound type of eliminator and indicates the double-eddy current flow in the concentrating chamber and in the cyclone. In both instances, the influence is outward at the meeting of the eddy-currents, and the cleansed gas is discharged at this zone.

The cyclone is different from the earlier art in (*a*) low position of gas inlet to the top cylinder, (*b*) low position of the mouth of

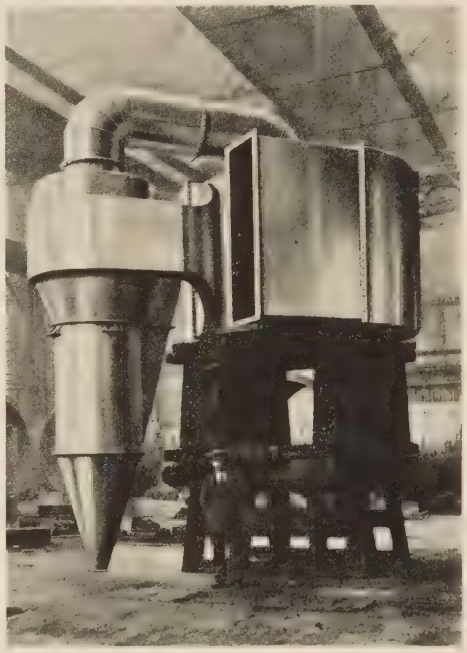

Fig. 1 Compound Type of Buell Dust Eliminator

the outlet pipe, (*c*) by-pass dust channel, and (*d*) increased ratio of overall height to a diameter of top cylinder.

Providing these features in the design gives a dust-concentration space above the gas inlet and permits a steady shaving off of dust from this zone for by-passing through the outside dust channel, which is located away from the mouth of the outlet pipe. This dust reenters at the mid-cylinder and the downward flow of the lower half of the double-eddy current promotes the travel of this dust to the bottom dust outlet.

Fig. 3 is a performance curve expressing the relation between particle size of fly ash and collection efficiency. This has been developed from reports of independent engineers who were retained by purchasers in connection with acceptance tests and includes eliminators having unit capacities as high as 118,000 cfm. As collection efficiencies ranging from 90 to over 93 per cent have been reported for particles of the 20-micron size and similar

values of between 82.4 and more than 86 per cent have been reported for the 10-micron sizing, the values shown on the curve are conservative. Many tests showed average collection-efficiency variations of less than 0.4 per cent for the various particle sizes according to the character of combustion origin, whether pulverized coal, stoker-fired coal, or stoker-fired lignite. These efficiencies were attained with a draft loss of less than 1.6 in. of water and a gas temperature of 400 F. With the knowledge that this eliminator has readily collected 90 per cent of the 20-micron size particles, a guarantee, as suggested by Dr. Schoene,

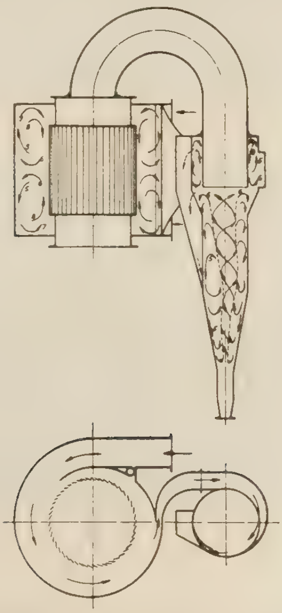

Fig. 2 Establishment of Double-Eddy Current Flow in the Concentrating Chamber and the Cyclone

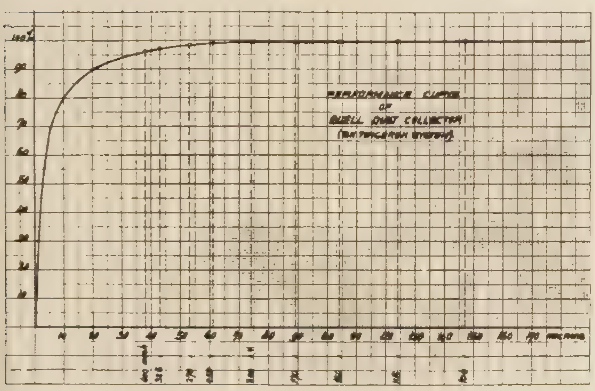

Fig. 3 Performance Curve Based on a Number of Acceptance Tests by Independent Engineers

regarding the collection of 90 per cent of all particles of 20-micron size and larger would be easily fulfilled.

Fig. 4 gives additional data of interest relating to the cyclone collector of the Buell system. These two curves relate to cyclones of similar design, with the exception that the cyclone represented by the lower curve has no dust by-pass system, whereas the

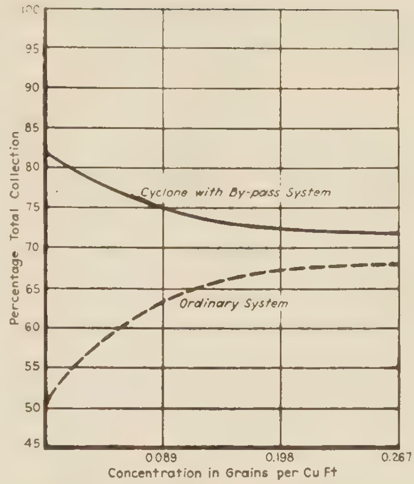

Fig. 4 Comparison of Collection Efficiency of Two Different Types of Cyclone at Various Dust Concentrations

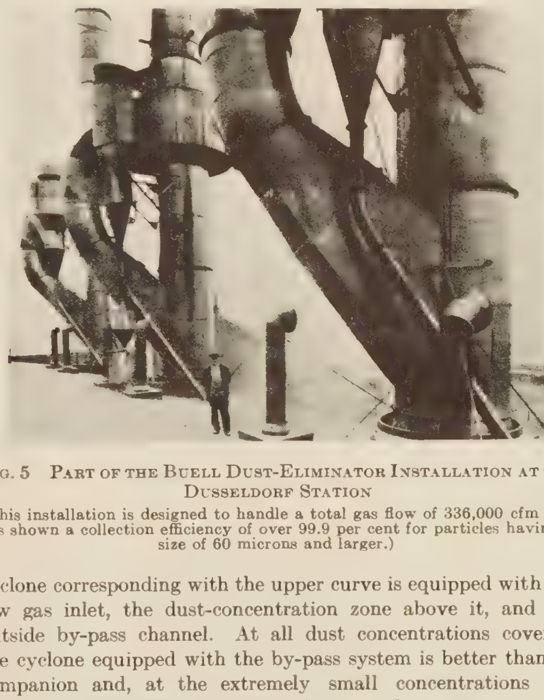

Fig. 5 Part of the Buell Dust-Eliminator Installation at the Dusseldorf Station

(This installation is designed to handle a total gas flow of 336,000 cfm and has shown a collection efficiency of over 99.9 per cent for particles having a size of 60 microns and larger.)

cyclone corresponding with the upper curve is equipped with the low gas inlet, the dust-concentration zone above it, and the outside by-pass channel. At all dust concentrations covered, the cyclone equipped with the by-pass system is better than its companion and, at the extremely small concentrations the efficiency characteristic is distinctly upward.

Fig. 5 shows part of the installation at the Dusseldorf station, which has a total of six collectors for an overall gas flow of 336,000 cfm. An independent engineering report on this station cited a collection of more than 99.9 per cent for all particles of 60 microns, approximately 250 mesh, and larger. This being a stoker-fired plant, the extremely small micron sizings were not considered of importance in the test.

In the matter of selective elimination, if the extreme fines are unnecessarily collected, the expression "What are we going to do with it after we catch it" is only magnified. In conclusion, the value of an eliminator should be rated directly in terms of its ability to collect the ash within the nuisance range.

Utilization of Pulverized-Fuel Fly Ash

By J. R. JAMES,[1] DETROIT, MICH.

THE TRENTON Channel plant of The Detroit Edison Company accumulates approximately 500 tons of fly ash per week by Cottrell precipitators. For the last several years, this company has carried on a number of investigations to find a method that would return at least enough revenue to pay for the handling of the ash on the property. Today, two outlets indicate considerable promise. One of these is what may be called a new kind of concrete, and the other is the manufacture of a building unit that is designated as Cottrell block.

The new concrete is made by mixing 100 lb of portland cement, 100 lb of dry fly ash, and approximately 340 lb of crushed cinders with the proper quantity of water. In 28 days, the resulting concrete shows a strength in compression of 3000 lb per sq in. To be conservative, the cost of this concrete will not be more than the ordinary stone or gravel concrete, and probably it will be slightly less. The real benefit to be derived from its use will be the reduction in the weight of a building which is reflected in reduced costs in foundation work. At present, no detailed practical information about this concrete is available, but The Detroit Edison Company plans to use it in the floor system of a six-story office building that will soon be built, so that, six months from now, some authentic information regarding this material will have been secured.

Our company has been developing Cottrell block for over three years under a patent controlled by the Rostone Company, Lafayette, Ind. This development work was carried on in a small plant with standard-size equipment which was set up in the basement of the Trenton Channel plant boiler room. Progress of this development has centered principally about the construction of a suitable machine for making these blocks as a commercial article. The estimated cost of a new plant manufacturing 8600 units in 24 hr is approximately $40,000.

Disposal of fly ash would be facilitated by using both of these outlets in conjunction with each other. The natural assumption is that the maximum volume of concrete will be poured in the warm months of the year, which leaves the winter months for the manufacture and accumulation of building blocks for the ensuing year's construction.

The overall heat-conductivity coefficient for an 8-in. wall of this material, in a 15-mph breeze, is 0.383 Btu per sq ft per hr per deg F difference in temperature. If the wall is furred and plastered on the hot side, the coefficient becomes 0.26. When hollow cells are filled with rock wool, the coefficient is 0.16, and by substituting fly ash, the coefficient is 0.18. In a fire test conducted at the Delray plant, a wall of Cottrell block was subjected to a 3-hr fire test, with 1600 F as the maximum temperature and then quenched with a fire hose, without destroying its structural value. However, some small shrinkage cracks about 1/8 in. deep did develop. Absorption will run about 6 per cent.

Fig. 1 Interior of a Church That Was Built of Cottrell Block

Fig. 2 Exterior of a House Built of Portland Cement Painted Cottrell Block

At the Trenton Channel plant is a garage which was built over three years ago. No ill effect from frost action can be observed. Numerous other structures have been built with Cottrell block. Fig. 1 is an example of a painted Cottrell block interior. The large home, shown in Fig. 2, has an exterior of portland cement painted Cottrell block. Smaller homes have 8-in. Cottrell block walls painted on the outside and a painted interior. The cells in the block are filled with ash. As the owners are well satisfied with the purchase price of $3500, including two acres of land, this block should appeal to low-cost housing projects.

[1] Senior engineer, civil- and mechanical-engineering design, The Detroit Edison Company. Mem. A.S.M.E. Mr. James received the degree of C.E. from the University of Michigan in 1911 and, for the next eight months, was principal assistant on a magnetic survey of the Great Lakes for the U. S. Lakes Survey. He was engaged in the design of hydroelectric projects for Gardiner S. Williams, Ann Arbor, Mich., for the next year and, in this connection, acted as field-construction supervisor for the 1500-kw Argo plant of The Detroit Edison Company. From January, 1913, until April, 1914, Mr. James was in charge of appraisal of overhead lines for the Eastern Michigan Edison Company, which company merged with The Detroit Edison Company in 1916. Upon the completion of this work, he accepted a position of draftsman with his present company, being promoted to engineer and assistant draftsman and, in 1925, became senior engineer in the engineering division.

The Cinder and Fly-Ash Public Nuisance

By WILLIAM G. CHRISTY,[1] JERSEY CITY, N. J.

THOSE of us, who are interested in the problems of air pollution, are glad to see discussions such as this on the programs of the A.S.M.E. We are also pleased to see the increased interest in this question. Use of pulverized coal, increase in the

[1] Hudson County smoke-abatement engineer. Mem. A.S.M.E. Mr. Christy received the degree of M.E. from Cornell University in 1911 and spent the next year with the Heine Safety Boiler Company as a designing, estimating, and testing engineer. From 1912 to 1915, he was assistant to H. H. Humphrey, consulting engineer at St. Louis, Mo., where he prepared plans and specifications for power plants, heating and ventilating systems, and mechanical and electrical equipment for office buildings, hospitals, hotels, factories, and similar structures. For the next two years, he conducted a manufacturers' agency in St. Louis, and handled heating specialties and power-plant

size of stokers, and greater rates of burning solid fuel have resulted in a tremendous increase in the discharge of solids from stacks in recent years. The public is demanding that something be done.

Suitable Means for Accurate Cinder Measurement Urgently Needed

Primarily a need exists for suitable means of accurately measuring the percentage of cinders and fly ash in a gas stream. Our Power Test Code Technical Committee on Dust Separating Apparatus is now working on this problem and hopes to establish standards for both measuring and testing. The problems of measuring solids in gas streams and testing equipment for their removal really come down to determining the best methods of obtaining representative samples. The time is now here when legislation and regulations, defining and limiting the discharge of solids from chimneys, are likely to be adopted. Such requirements should be reasonable. They should give the public relief and at the same time not cause too much hardship on industries and utilities.

The Smoke Prevention Association is a national organization of smoke commissioners, smoke inspectors, railroad men, and others interested in fuel economy and smoke abatement. At present, the Public Service Committee and the Standards Committee of this organization are working on the problem of establishing standards of measuring and regulating the discharge of cinders and fly ash into the atmosphere. I feel sure that I voice the sentiments of the members of the Association when I say that we would welcome the cooperation of this Society.

Not much legislation on this subject exists at present. Some ordinances prohibit excessive discharge of fly ash and cinders and some of these specify that such solids be measured by the Ringelmann chart. This chart was really not intended for measuring fly ash and is not suitable for that purpose. Other ordinances classify excessive discharge of solids from stacks as a nuisance, but this is also unsatisfactory. Such a regulation is subject to different interpretations.

Cinder Deposits a Nuisance and Possible Cause of Damage

It should be needless for me to emphasize that the deposit of cinders and fly ash is a nuisance and may cause considerable damage. Some two years ago, I had occasion to investigate the discharge of fly ash from a plant fired with pulverized coal. The principal complainant was a truck farmer, whose farm was approximately one-half mile east of the plant. Apparently, his crops were being ruined by the excessive deposit of fly ash due to the prevailing winds from the west. Along the edge of some timber was land that had not been cultivated. In this location, I saw a deposit of fly ash $2^1/_2$ in. thick, the worst I have ever seen. The deposit was the result of some seven or eight years' operation of the plant. A corporation, whose officials have any civic pride, should want to reduce materially such a discharge, irrespective of any legislation.

My hope is that discussions such as this and the work of the A.S.M.E. Power Test Code Committee No. 21 will enable us to arrive at a basis for sane legislation. Surely, all of us agree that something must be done. Mechanical engineers ought to make this their responsibility. Otherwise, legislation may be passed which is not based on engineering practice, is impractical, or may work undue hardships.

Fly-Ash Removal and Smoke-Abatement Problems Demand Solution

From the standpoint of the public, this problem is one that must be solved. With powdered-coal plants, some sort of fly-ash removal apparatus is surely necessary. I feel that the time is not far distant when most stoker-fired boilers and furnaces will have flue-gas scrubbers or cinder catchers.

The term "smoke abatement" is really a misnomer; it means much more than the elimination of visible smoke. The name "Pure Air" which was used to designate the A.S.M.E. committee always appealed to me. Smoke-abatement engineers are interested in eliminating all kinds of air pollution and really getting pure air to breathe. It is much more than a question of good combustion. It means a drastic reduction of fumes, sulphur gases and solids from stacks and open fires.

---

equipment. From 1918 to 1920, he was associated with the U. S. Shipping Board, first as a production engineer and later as a district supply manager. From 1920 to 1922, he was superintendent and field engineer of the St. Louis Boat and Engineering Co., having charge of the construction of four large Mississippi River towboats. He then became associated with F. H. Schubert in the Schubert-Christy Construction and Machinery Co. of St. Louis. While Chairman of the St. Louis Section, A.S.M.E., in 1925, he was one of the organizers of the Citizens Smoke Abatement League of St. Louis, and served as its executive secretary for two years.

Determination of the Relative Resistance to Cavitation Erosion by the Vibratory Method

By S. LOGAN KERR,[1] PHILADELPHIA, PA.

The cavitation-erosion tests described in this report were made under the direction of the mechanical section, U. S. Engineer Office, Eastport, Me., at the Massachusetts Institute of Technology, Cambridge, Mass., by Prof. H. Peters. The investigation was part of the materials-corrosion investigation, made to provide an accurate basis for the selection of the proper materials to be used in the construction of the large hydroelectric units required on the Passamaquoddy project. No information was available upon the cavitation resistance of materials in sea water as compared with their behavior in fresh water. The program included tests on 80 materials in a newly developed vibratory apparatus and the behavior of three materials in the venturi-type apparatus used for previous investigations. Reliable results were obtained on the behavior of materials in sea water as compared with fresh water, and the relation between cavitation damage and temperature was established.

ONE OF the most troublesome of the operating difficulties encountered with hydraulic turbines or centrifugal pumps has been pitting or eroding action caused by cavitation on blades and other portions of machinery subjected to high-velocity flow. Research investigations on this phenomenon have followed two separate lines

(1) Effect of cavitation upon efficiency or performance
(2) Destructive effects of cavitation upon materials

The *first* group covers elements which are functions of turbine or pump design, and the responsibility rests quite properly with the manufacturers to insure against faulty performance due to cavitation. If model turbines or pumps are constructed and tested under varying conditions of draft head or suction lift, the characteristics of those particular types can be established and information secured which governs the design of the structures in which they are to be installed. Many articles have been published recently describing the general theory of cavitation and the testing of laboratory models.

The *second* group dealing with relative rates of erosion of various metals by cavitation has also been the subject of some research. A limited volume of test information is available in regard to the behavior of various materials in fresh water, but no data could be found which gave the damage from cavitation in sea water as compared with that experienced in fresh water.

It has been found from experience that, in localized areas, cavitation can be set up which is not of sufficient magnitude to reduce the efficiency or to affect the performance of the unit but is sufficiently intense in many cases to cause destructive pitting on the blades or throat rings and to require maintenance at frequent intervals. The cost of maintaining and repairing large units and the loss of output during the repair period make it essential that suitable erosion-resisting metals be employed in the portions of the turbines where high velocities and potential cavitation damage might be found.

Purpose of the Investigation

In connection with the Passamaquoddy Tidal Power Development at Eastport, Me., a materials-corrosion investigation[2] was instituted to select the materials suitable for use in the various structures and equipment exposed to the action of sea water or salt air. In this investigation, three principal factors were considered

(1) Corrosion of metals in sea water
(2) Electrolytic action between dissimilar metals in sea water
(3) Resistance of various metals to the erosive action of cavitation

Only the third phase of the investigation is covered in this article, the results of the first and second portions are not yet available as the exposure tests are being continued until June 30, 1937, at least. From the information secured in this investigation, it was expected that the materials for constructing the turbines, gates, and other portions of the equipment could be selected to give the longest life at the least cost.

Definition of Cavitation Action

For many years, pitting on the suction side of hydraulic-turbine runners and of pump impellers was thought to be due to a chemical action which resulted from the release of dissolved oxygen in the water. Investigations made in England with marine propellers some years ago indicated that the action was mechanical rather than chemical and that it was caused by a rapid fluctuation of pressure due to the repeated formation and collapse of vacuum pockets adjacent to the blades.

With cast iron, this action proceeds very rapidly, as the material is naturally porous, the softer portions are eaten away, and

[1] Manager, Chemical Engineering Division, United Engineers & Constructors Inc., Philadelphia, Pa. Mem. A.S.M.E. Mr. Kerr was graduated from the University of Pennsylvania in 1921 with the degree of B.S. and, in 1924, with degree of M.E. Upon graduation, he entered the I. P. Morris Division of the William Cramp & Sons Ship & Engine Building Co. as research assistant. In 1924, he was appointed assistant hydraulic engineer and, in 1927, assistant chief engineer. From 1929 to 1935, he was research engineer in charge of experimental and field tests and development work on hydraulic turbines, governors, valves, and other equipment. In 1935 and 1936, he was senior mechanical engineer, U. S. Engineer Office, Eastport, Me., having charge of research and design work in connection with the mechanical equipment for the Passamaquoddy project. At present he is in the Chemical Engineering Division of United Engineers & Constructors Inc., Philadelphia, Pa. Mr. Kerr is 1936–1937 Chairman of the A.S.M.E. Hydraulic Division and of the A.S.M.E. Committee on Water Hammer.

Contributed by the Hydraulic Division and presented at the Joint Meeting of the Applied Mechanics and Hydraulic Divisions of The American Society of Mechanical Engineers, Ithaca, N. Y., June 25–26, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date.

[2] For description of the investigation, scope of studies, laboratory facilities, and results of tests, see Interim Reports of U. S. Engineer Office, Eastport, Me., dated Feb. 15 and Oct. 15, 1936.

the harder sections remain, giving the characteristic "pitted" appearance. With cast steel, the action is much the same, but, due to the higher fiber strength and denser structure, it does not proceed as rapidly. With cast bronze, the grain structure is also dense and, although the pitted appearance is not as pronounced, the vanes have a sandblasted appearance where cavitation is present.

With alloy steels of high strength and extremely dense grain structure, the resistance to cavitation damage has been found to be very high, but these materials are extremely expensive and are difficult to secure in the cast form.

Methods of Test

Accurate determination of the relative resistance of materials to cavitation erosion presents many difficulties, as the rate of erosion experienced in the field is slow and operating conditions vary considerably. Testing of model turbines constructed of

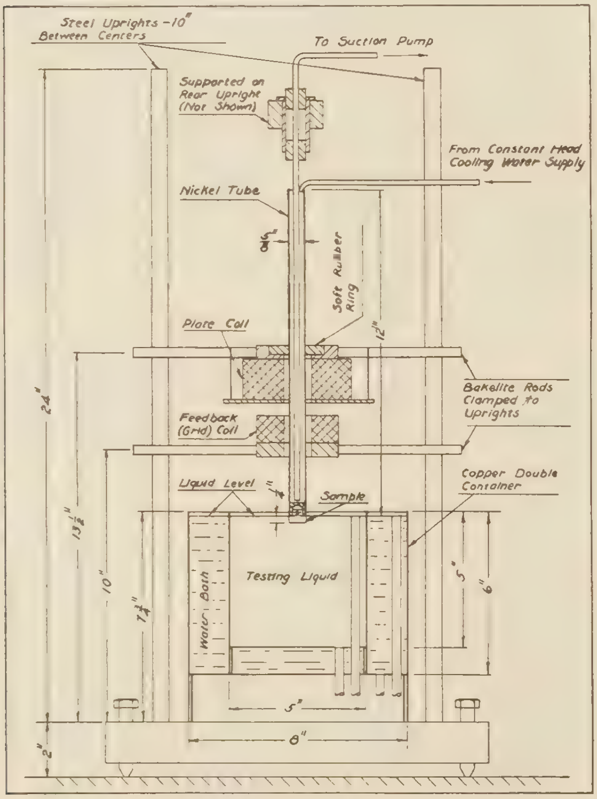

Fig. 1 Vibratory-Type Cavitation-Testing Apparatus

different metals does not appear to be feasible due to the cost involved. Cavitation action of great intensity can be produced in the laboratory by passing water at high velocity through a restricted area followed by a more or less sudden enlargement. Early types of cavitation-testing apparatus were in the form of a venturi tube, and this name is generally used to designate that type of test unit, although newer and more efficient throat profiles have been developed in the United States and Europe.

The first experimental unit of the venturi type in the United States was constructed in the Massachusetts Institute of Technology, and a second unit added a short time thereafter. The Safe Harbor Water Power Corporation sponsored this work, and it has since set up similar venturi testing units at Holtwood, and Safe Harbor, Pa. Results of this investigation are given in the paper[3] by J. M. Mousson.

Had this method been employed in the investigation for the Passamaquoddy project, a minimum period of one year would have been required to test about 50 different materials, one specimen being tested in fresh water and one in sea water. The time available for this experimental program, based upon the tentative construction schedule, was only a few months, and a more rapid method was required.

In the spring of 1935, investigations had been under way at the Massachusetts Institute of Technology utilizing a somewhat different method of cavitation testing, as shown in Figs. 1 and 2, whereby the metallic sample was vibrated at high frequency to simulate a very intense local form of cavitation. By the summer of 1935, this had progressed to the point where Dr. J. C. Hunsaker and Dr. H. Peters of the mechanical-engineering department of Massachusetts Institute of Technology felt that reasonably accurate results could be secured on the relative resistance of various materials to cavitation erosion.

The vibratory apparatus, Fig. 1, consisted of a vacuum-tube oscillator used for producing an alternating magnetic field in which was placed a nickel tube that vibrated longitudinally at its natural frequency under the action of this magnetic field.

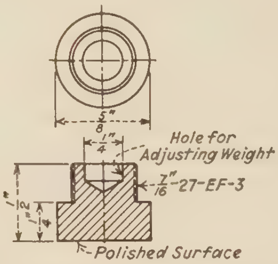

Fig. 2 Vibratory-Type Test Specimen

The specimens were attached to the end of the nickel tube and were immersed in the test fluid, care being taken that the depth of immersion was maintained constant at $^1/_4$ in. The test container was set in a water bath to maintain a constant temperature throughout. The nickel tube was cooled by a fine spray of water which was withdrawn from the bottom of the tube by a small suction pump.

This vibratory apparatus was developed by Dr. Newton Gaines and is described in his article[4] entitled, "A Magnetostriction Oscillator Producing Intense Audible Sound and Some Effects Obtained." A description of its use for cavitation testing is given by Dr. J. C. Hunsaker in his paper[5] "Progress Report on Cavitation Research at Massachusetts Institute of Technology."

In the fall of 1935, the method was investigated by the writer for the U. S. Engineer Department, and preliminary tests were found to be sufficiently reliable for the determination of the relative resistance of these various materials to cavitation.

While this new vibratory method had never been utilized previously for any extensive commercial research or investigation programs, a detailed study of the apparatus and of preliminary test results indicated that results could be duplicated accurately, the time element for the complete investigation could be reduced to a few months, and the cost of operation was about one tenth

[3] "Pitting Resistance of Metals Under Cavitation Conditions," by J. M. Mousson, to be presented at the Joint Meeting of the Hydraulic and Applied Mechanics Divisions of The American Society of Mechanical Engineers, Ithaca, N. Y., June 25–26, 1937.

to one fifth of that estimated for the normal venturi method. The vibratory apparatus also had the unique advantage that the fluid could be changed readily, permitting a careful study of the relative damage in fresh and sea water.

A contract was arranged between the U. S. Engineer Office at Eastport, Me., and Massachusetts Institute of Technology to cover the testing of a number of specimens by the vibratory method and to check the relative results obtained in this manner with tests of a limited number of the same materials in the venturi apparatus at the Institute for previous research work.

Preliminary Tests

With such a new method of test, careful calibrations were essential. Maximum and minimum rates of weight loss, design of specimen, proper length of exposure, and many other problems immediately presented themselves. Preliminary tests demonstrated at once that results were remarkably consistent, temperature and type of solution had a marked effect upon rate of erosion, and many materials behaved differently at the outset of the test period from what they did after an appreciable time of exposure.

Four materials supplied by the Institute were used in these calibrations, namely, brass, cold-rolled steel, cast iron, and stainless steel. Two specimens of each material were tested for 2 hr, with weight losses determined at the end of each half-hour during the test. Fig. 3 gives the results of these tests. It was found that the test period could be reduced to 90 min, with intermediate weight determinations at the end of each 30 min of exposure.

Some changes in apparatus were necessary, but after a few disappointing experiences, the equipment was arranged to operate continuously from 8 a.m. to midnight, employing two shifts of observers. The first tests were made in March, 1936, and the program was completed July 15, 1936.

Methods of Securing Samples

Various manufacturers of turbines and pumps, as well as a group of foundry companies and other organizations, had already been approached in regard to the materials-corrosion investigation, and corrosion-test specimens for the Eastport laboratory had been secured from most of these organizations. A special information circular, dealing entirely with cavitation-resistance tests, was prepared and forwarded to manufacturers about Dec. 14, 1935. A brief description of the vibratory method was given, and a request for cavitation-test specimens was made of all organizations which had furnished corrosion specimens for the Eastport laboratory.

Response to this inquiry was very satisfactory, and 98 different materials were submitted for test. Funds were available for testing only 50 of the specimens submitted, and it was necessary to establish a priority list that included only those materials which had already been submitted for corrosion tests. From these were selected first, the materials submitted by turbine manufacturers; second, those submitted by pump manufacturers; and third, special materials deemed necessary to cover the field satisfactorily. It was later found possible to test 80 different materials and conduct additional tests to determine the effect of temperature, different concentrations of salt water as compared with natural sea water, and the protection afforded by noncorrosive coatings.

To simplify comparisons and to divide the large number of materials into groups, a classification was set up applying to the corrosion testing as well as the cavitation testing. The classifications used and the number of specimens in each class are given in Table 1.

Each different material was assigned a serial number, and each individual specimen had an identifying letter or a combination of letters and numbers to coordinate the records and keep the identity of the manufacturer confidential. Trade names have been eliminated from the records, and, for certain materials, only the approximate composition is given, although, in most cases, the certified chemical analysis is published. Written permission was obtained from each manufacturer for the release of data pertaining to his materials to be included in the published reports of the tests.

In the check tests by the venturi method in both salt and fresh water, three materials, cast iron, class 10, serial 82; cast steel, class 13, serial 118; and manganese bronze, class 5, serial 76, were selected. An additional test was made in fresh water only with a chrome-nickel steel, class 17, serial 132. No venturi test

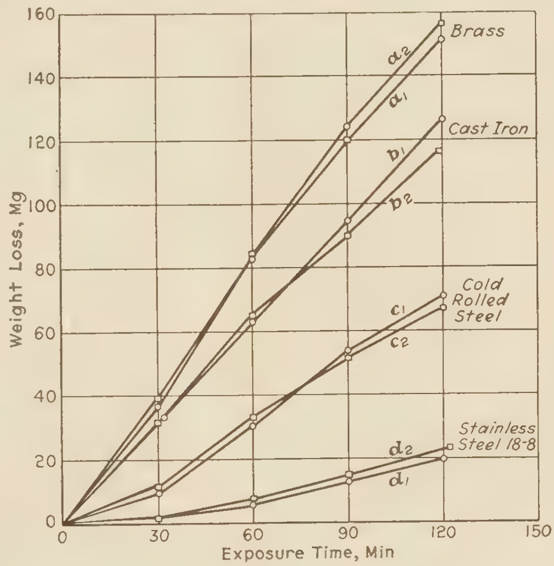

Fig. 3 Preliminary Calibration-Test Curves
(Weight of sample = 13 g; water temperature = 20 C.)

was possible on this material in sea water owing to lack of time and of funds.

Specimens

The design of the vibratory-test specimen was investigated very carefully, and five different brass specimens, varying in weight from 8 to 16 g, were tested. It was found that the total weight loss at the end of 30 min was practically the same, irrespective of the initial weight. The convenient value was found to be about 13.5 g and all specimens were adjusted to fall within 1 g above or below this weight.

As shown in Fig. 2, each specimen was $^5/_8$ in. in diameter and $^1/_4$ in. long with a threaded extension $^7/_{16}$ in. in diameter and $^1/_4$ in. long which was used to attach the specimen to the oscillating nickel tube. A small hole, $^1/_4$ in. in diameter, was drilled in the threaded end of the specimen to adjust the weight to the standard range and thus compensate for differences in densities of material. The face was carefully polished to secure as uniform a surface as possible for exposure to cavitation. These specimens were prepared in the machine shop at the Massachusetts Institute of Technology. Six specimens of each type were normally available, although, in most cases, only four specimens were prepared unless special tests were called for.

Test Procedure

The general procedure consisted in setting up a dummy specimen which would oscillate for approximately 15 min to bring the

[a] Minimum of values to be expected.

air content of the water to a constant value. The dummy was then removed, and the test specimen inserted after having been carefully weighed on a precision balance sensitive to 0.25 mg.

The apparatus was vibrated for 30 min, the test specimen removed, another specimen inserted, and the first specimen carefully dried and weighed to determine the quantity of material eroded by cavitation. This process was repeated three times securing accurate values of weight loss at the end of 30, 60, and 90 min. A few tests were made taking measurements at intervals of 5 or 10 min for the first half-hour to determine more accurately the behavior in this range (Fig. 6).

Upon completion of the 90-min test period, the specimen was photographed with an enlargement of approximately 6 diameters, and the Rockwell hardness (B scale) measured on the periphery of the specimen.

The air content of the water was measured frequently during the tests. It decreased in the fluid during the initial part of the vibratory period, and the equilibrium points, in fresh water about 1.16 per cent air content and in sea water at 1.00 per cent, were reached after approximately 30 min (Fig. 4). These values are somewhat below the corresponding fresh-water saturation value of 1.6 per cent at 25 C.

Calibrating specimens of brass made from the same piece of rolled bar were employed from time to time to make certain that characteristics of the apparatus did not change during the investigation. The atmospheric pressure was measured repeatedly, but as far as could be established, slight variations did not influence the results to any noticeable extent.

Sea Water Used in Vibratory Tests

Sea water used in the vibratory tests was taken from three locations in Cobscook Bay, Eastport, Me.

Salinity, density, and hydrogen-ion concentration (pH), were measured in Eastport by the concrete laboratory staff, and density and air content were measured at Massachusetts Institute of Technology as a check upon the condition of the water during the test.

A typical analysis of sea water from Cobscook Bay is as follows:

	Grams per liter
Sodium (Na)	9.95
Magnesium (Mg)	1.50
Calcium (Ca)	0.41
Chloride (Cl)	17.83
Sulphate (SO_4)	2.54
Bromine (Br)	0.06
Potassium (K)	0.33

Density averages 1.023, and hydrogen-ion concentration (pH), varies from 8.0 to 8.1, indicating a decidedly alkaline reaction. The water is free from contamination from sewage or industrial wastes, and very little fresh water flows into Cobscook Bay to dilute the sea water.

The general character of the sea water approaches that found in the open ocean. It is free from the acid reaction of the water in Boston Harbor, where the pH is about 6.0. The neutral point is 7.0.

Effect of Temperature on Cavitation

In various research investigations made previously, it was observed that some difference in performance and in cavitation damage occurred with variations in temperature. In the venturi apparatus, cooling or heating coils were used to maintain constant temperatures, but the great volume of water and the large quantity of energy dissipated in the venturi throat made this temperature control difficult. The time required for a given test was long, and it was not usually possible to investigate thoroughly the relation between cavitation damage and temperature with extreme accuracy.

In the preliminary group of vibratory tests made for the Eastport district, the fluid was maintained at a constant temperature of 20 C, and, later, another preliminary investigation, utilizing aluminum-alloy samples was made to study the effect of temperature upon weight loss. This investigation showed that the cavitation damage in a given time doubled when the temperature was raised from 0 to approximately 50 C. This same effect was found to hold true in the case of a concentrated saline solution having 20 per cent, by weight, of sodium chloride. Damage was greater in this solution than was the case with fresh water, but loss in weight still reached its maximum at about 50 C. As temperature was increased beyond this point, damage decreased until it approached zero at the boiling point.

The effect of temperature, therefore, had to be considered carefully in this investigation, and the program was arranged so that the vibratory tests were run at a constant temperature of 25 C representing approximately the average between conditions at 0 C and maximum damage at 50 C.

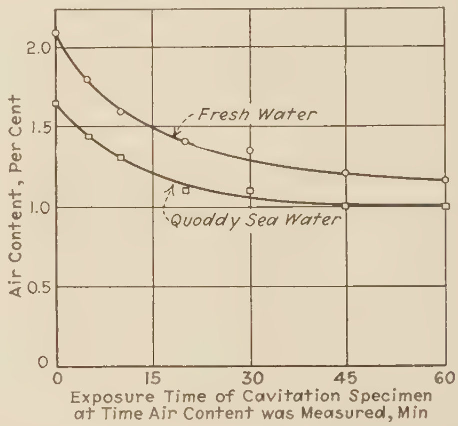

Fig. 4 Curve of Air Content With Respect to Time

(Air content = V_A/V_w, where V_A = volume of air dissolved in the water and V_w = volume of water tested. All volumes reduced to standard conditions of temperature and pressure, 0 C and 760 mm of mercury. Temperature of water during cavitation = 25 C. Corresponding air content of fresh water used in test = 1.6 per cent at saturation.)

The container holding the fluid, in which the specimen was vibrated, was kept in a constant-temperature bath, and variations from this constant temperature were held within very narrow limits. All tests were carried on for the standard time interval of 90 min, with intermediate weighings at 30 and 60 min. Following completion of the main group of vibratory tests, five different materials were selected for temperature studies; namely, brass, cast iron, and cold-rolled steel, which were tested in the original calibration studies; cast steel, serial 94; and cast iron, serial 105. The tests were made at 3, 14, 25, 38, and 50 C with both fresh and salt water. It was found that damage to specimens in fresh water reached its maximum at about 25 to 30 C for brass, whereas for the cast irons and the steels, the maximum condition appeared to be at or beyond 50 C. An insufficient number of tests was made to establish this relation definitely, but it was apparent that low-temperature conditions had a tendency to reduce the destructive effect and that there was a general tendency for this destructive effect to increase with temperature up to a certain point and then to decrease with still higher temperatures.

Corresponding tests were made in sea water for brass, cast iron, and cold-rolled steel, and in artificial sea water for cast steel, serial 94, and cast iron, serial 105. The same general behavior

was observed, but, in the case of both types of cast iron, damage at low temperatures was much greater in sea water than in fresh water.

The preliminary investigation combined with the later studies would indicate that change in cavitation damage with temperature is due to change in air content or vapor pressure or a combination of both. Colder water has the ability to dissolve more oxygen and other gases from the air, and these tend to go out of solution when subjected to the high-vacuum conditions that accompany cavitation, thus forming an air-cushion which reduces the force of the counterblow, and, hence, decreases cavitation erosion. As the temperature is increased, more and more of these dissolved gases are driven off, the return blow caused by collapse of the vacuum pocket is not cushioned, and the destructive effect is increased.

As the temperature is raised still further, the vapor pressure of the water or other fluid increases, and the vacuum pocket becomes filled with increasing volumes of water vapor. As the temperature approaches the boiling point, almost all of the force of the return blow is apparently absorbed by the cushioning action of the "steam," and, hence, the cavitation damage becomes negligible.

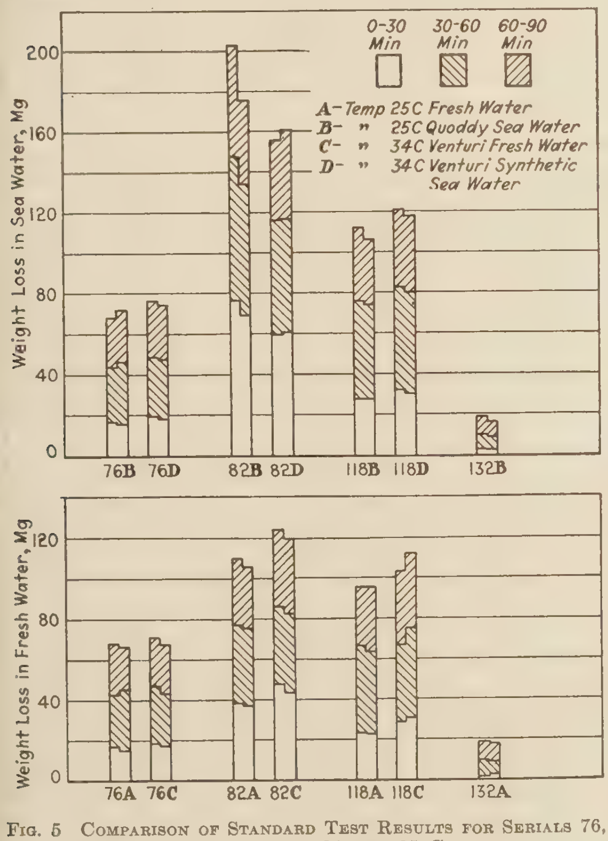

Fig. 5 Comparison of Standard Test Results for Serials 76, 82, and 118 at 34 and 25 C

For hydroelectric plants, the water temperature rarely exceeds 35 C and will usually be between 0 and 25 C. On the Passamaquoddy project, temperature of the water would rarely rise above 15 C, and, hence, selection of a standard temperature of 25 C represented conditions that approach maximum damage which would normally be found in such plants. The change in temperature from 25 C, which was the standard for the laboratory test, up to 34 C, which was the standard for the venturi testing, did not introduce any major discrepancy. In the case of serials 76, 82, and 118, a direct comparison (Fig. 5) has been shown of the destruction from 0 to 90 min in both fresh and sea water at these two different temperatures.

With pumping machinery, where water delivered to the suction side of the pump comes from a large reservoir or from the ocean, it is doubtful whether the temperature will exceed 35 C. Where pumping equipment is used in process industries or for handling boiler feedwater, these temperatures would naturally be greatly exceeded. The release of water vapor may reduce cavitation

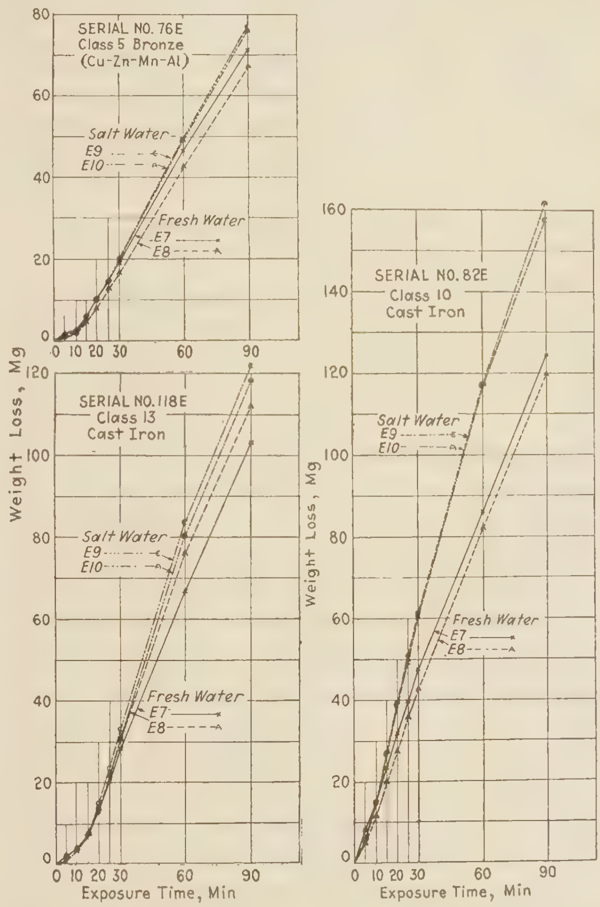

Fig. 6 Vibratory-Test Curves for Serials 76, 82, and 118 (These cavitation-erosion curves by the vibratory method were made simultaneously on the same materials tested by the venturi apparatus and maintained at the same temperature of 34 C. Standard vibratory tests at 25 C were also made and a comparison of the results is shown in Fig. 5.)

damage appreciably, but, at the same time, the high-vacuum conditions at suction could cause a change in pump characteristics which might impair its efficiency greatly, even though the blades were not being damaged by cavitation.

Effect of Pressure on Cavitation

It is important to note that all of these vibratory tests have been made at atmospheric pressure. If the pressure were increased, the entire phenomenon might be changed, as water would be held against the surface of the specimen, and, thus, the tendency toward formation of vacuum pockets would be reduced. It is a well-established fact that severe cavitation can be corrected by an increase in the back pressure on the turbine, or by an increase in suction pressure on a pump.

At the naval model basin located in the Washington, D. C., Navy Yard, marine propellers are tested under various conditions of flow and pressure. Cavitation can be eliminated almost entirely if absolute pressure of the water with respect to the propeller blade is increased sufficiently. The opposite effect is noted if pressure is decreased, as cavitation areas form and gradually reach sufficient proportions to change flow conditions past the blades and, thus, impair the effectiveness of the propellers. This same basic relation holds true in hydraulic turbines and pumps, and it also applies in the venturi type of cavitation-testing apparatus, since a sufficiently high back pressure will hold the flow against the walls of the tube and prevent the formation of the vacuum pockets.

Detailed research on the effect of varying pressures in the vibratory apparatus has not yet been undertaken, but it is probable that cavitation damage will be reduced if a substantially higher pressure than atmospheric is exerted on the surface of the liquid. It was noted that the very small variation in atmospheric pressures experienced during the Eastport District tests made no measurable difference in damage due to caviation.

Effect of Variations in Fluids Upon Cavitation

In preliminary investigations undertaken by Massachusetts Institute of Technology, prior to the contract with the Eastport District Engineer Office, tests were made with aluminum-alloy samples in the vibratory apparatus, using fresh water, a 20 per cent solution of sodium chloride, and a solution of methyl alcohol. The denser liquid caused greater damage, and the volatile liquid, such as alcohol, caused relatively small damage due probably to high vapor pressure and cushioning of the cavitation blow by a pocket of vapor. Previous discussion in regard to variation of cavitation damage with temperature is further amplified by tests using different fluids.

With sea water, cavitation damage has usually been slightly greater than with fresh water, particularly with soft or porous materials, and is very pronounced with cast iron. This greater proportional damage with cast iron and some cast steels is undoubtedly due to a combination of the changes in density, air content, and vapor pressure but must also be influenced by the highly corrosive action of sea water upon ferrous materials.

Measures of Pitting

There is no established measure or unit of comparison for cavitation damage, although many attempts have been made to set up some means of evaluation. With hydraulic-turbine installations studied by the hydraulic power committee of the National Electric Light Association, cavitation damage[6] was grouped roughly into three classes: The first class, designated as "no pitting," included wheels showing little or no pitting in 10 years' service, with a probable life of 20 years without repairs. The second class, "moderate pitting," included those wheels whose life could be extended to 20 years by minor repairs. The third class, "excessive pitting," comprised wheels requiring replacement in less than 10 years. This method was open to differences of opinion between manufacturers and purchasers of equipment, and cases were found where pitting, which covered relatively small areas and did not affect the strength of the runner, was designated as "excessive pitting," calling for replacement within 10 years. These designations were finally dropped from use.

The advent of electric welding permitted repair of cast-steel runners in place without the necessity of dismantling any equipment. In the case of cast-iron runners, some repair work was done in place, but this involved expensive work, owing to the difficulty of welding material onto cast iron. Some bronze runners were repaired in place, but, with both cast iron and bronze, it was frequently found simpler to replace the runner and carry on the repair work at a convenient location in the power house. This avoided a long shutdown of the unit and permitted a better final result.

The quantity of welding rod used in repairs by welding offered, for the first time, a means whereby cavitation damage could be measured. The "pounds of welding rod per runner" became the first unit of measurement. In some turbine contracts, a guarantee clause was set up which used some arbitrary value of weight of welded metal required for repairs to determine the liability of the manufacturer in correcting cases of pitting. This method also proved unpopular and is now rarely used.

Both of these early attempts to set up a measure of cavitation erosion were based upon actual damage occurring during operation and required a long time. They did not give assurance against pitting; moreover, the operating conditions such as draft head, percentage of load, and other vital characteristics did not remain the same on all units or at all seasons.

Better understanding of the nature of cavitation and growing use of tests of model turbines under varying conditions of draft head have permitted the predetermination of the effect of cavitation and made it possible to avoid much of the trouble previously experienced. With the advent of the venturi-type cavitation-testing apparatus, it was possible to measure for the first time, under standardized conditions, the actual weight of metal removed by the destructive action of cavitation. This varied with the size of specimen, the area affected, and with the size and the local conditions existing in the particular apparatus in which the tests were made. The weight loss which is determined from such tests is not always the absolute measure of damage, as plastic deformation may occur without a corresponding loss of material.

Preliminary Scale of Relative Resistance to Erosion

In outlining the program with the Massachusetts Institute of Technology, it was decided to set up a scale of relative resistance which would be based upon the weight loss of standard specimens at standard temperatures during accurately measured time intervals. Materials which lost the least weight would be placed at the top of the scale, and those which lost the greatest weight would be placed at the bottom.

One basis of comparison employed the weight loss of one particular material as a standard. Weight loss on this material was to be determined very carefully and considered equal to unity in the resistance scale. Serial 82, a common variety of cast iron with a carbon content of 3.3 per cent and small percentages of manganese and silicon, was selected. For the first 30 min, this material lost 37.9 mg, and this was made equal to unity in the relative scale for the period of 0 to 30 min. Measured weight loss for other materials in the same time was then divided into this standard weight loss, and the quotient represented the value of relative resistance. The highest value of relative resistance represented the most durable material, and the lowest value represented the material that suffers the most damage. The same method was used for periods of from 0 to 60 and 0 to 90 min, the standard weight losses being 75.2 mg for the former and 107.7 mg for the latter.

This relative-resistance scale had the disadvantage of being an arbitrary ratio, based upon some particular material. While the average weight loss of seven specimens of cast iron, class 10, was 37.1 mg and while this corresponded very closely to the weight loss of the particular type of material selected, it nevertheless was an artificial standard and one that could not be reproduced with ease.

[6] "Pitting of Hydraulic Turbine Runners," National Electric Light Association Publication No. 256–18, April, 1926.

Final Relative Resistance Scales

Another and more satisfactory method was developed as a result of study of the various test curves. It was noted that a number of materials, particularly those having high strength and dense grain structure, would not lose weight at a uniform rate throughout the entire 90-min period but would have a time lag and, for the first 30 min, would have a weight loss somewhat less than that experienced during each of the two subsequent 30-min intervals. This was found with practically all high-strength and forged materials, whereas, with low-strength or cast materials, the rate of weight loss was practically uniform from 0 to 90 min and, during the first 30 min, indicated no sign of the lag that was present with other types.

On three selected materials, serials 76, 82, and 118, behavior in the initial 30-min period was investigated after each 5 min of exposure from 0 to 30 min and for each 30 min thereafter. On the cast material, serial 82, cavitation damage progressed at a relatively uniform rate from the very beginning of exposure in the vibratory apparatus. Bronze, serial 76, indicated little or no damage in the first 5 min, but, at the end of 15 min, a relatively uniform rate had been established which continued for the remaining exposure time. In the case of steel, serial 118, this uniform rate was not reached until about 20 min. Fig. 6 shows the results of this study.

Inspection of all individual test results indicated that, at the end of the first 30 min, cavitation erosion was taking place at a relatively uniform rate, but, during the first 30 min, wide variations were present. This analysis led to the division of the vibratory-test work into two parts, namely, the period from 0 to 30 min giving an indication of the initial resistance to cavitation and, second, the period from 30 to 90 min representing the relative resistance to uniform continued cavitation erosion. By segregating results into these two groups, skin effect could be considered, and higher initial resistance to cavitation indicated from the data already obtained. Variation due to finish or heat-treatment may have a measurable effect upon initial breaking down of the surface, but, after the surface was once broken through, destruction would progress fairly uniformly and make its way at a steady rate through material of relatively constant density.

The nature of cavitation indicates the desirability of distinguishing between these two actions and, based upon the vibratory tests, two separate scales of relative resistance have been set up.

Scale 1. Relative resistance to erosion is the index of the uniform erosive or pitting action, which takes place after the ultimate strength or fatigue limit has been reached.

Scale 2. Initial resistance to erosion is an index of the plastic-deformation period prior to reaching the fatigue limit of the metal.

These were both based upon actual weight loss in milligrams rather than upon a ratio established with respect to some arbitrarily selected material. The unit of "milligrams per hour" could be used as all specimens in the vibratory series were of the same dimensions.

Accuracy

Reliability of the results depends upon four main factors

(1) Constant frequency of the vibrator
(2) Accuracy in the determination of weight losses
(3) Uniformity of the material
(4) Uniformity of composition and temperature of the fluid

Investigation showed that the vibratory apparatus was kept at a constant frequency of 6700 cycles per sec by using the natural frequency of the nickel tube. The amplitude of 0.09 mm was kept uniform by regulating the power input to the oscillator. It is believed that the vibration frequency and amplitude were maintained within 2 per cent above or below the normal value. Weight loss, particularly at the end of the 90-min period, was sufficient to insure accuracy within 2 per cent, and the materials tested seemed to be unusually uniform with very few exceptions. Where a major discrepancy occurred between results of two specimens, a third was usually tested, and the average used, unless some condition during test indicated that results from a particular specimen should be discarded.

Air content, temperature, and composition of the fresh and salt water were checked repeatedly, and the variations were found to be negligible.

Check tests indicated that an individual specimen might be shifted two places on the relative scales, but the average of tests of two specimens would probably prevent a shift of more than one place. The position of the average of one classification would be unchanged.

Index of Fatigue Limit

The time at which a uniform rate of weight loss is reached in the vibratory apparatus may indicate the transition point between conditions of plastic flow or of work hardening and the condition of pitting which occurs after the fatigue limit has been passed. It may be noted in Fig. 6 that the change in the rate of weight loss is not usually abrupt but is a gradual increase which occurs over a period of 10 to 30 min. Beyond this time, however, damage takes place at a relatively uniform rate for some appreciable time.

It is possible that behavior during the first half-hour of exposure in the vibratory apparatus may prove to be a convenient method by which the approximate fatigue point may be determined. Frequency of oscillation in the vibratory apparatus equals about 400,000 applications of stress per minute, and, for 30 min of exposure, this total reaches the enormous figure of 12,000,000. In a fatigue-testing apparatus operating at 1000 rpm, it would require about 200 hr or slightly over 8 days of continuous operation to equal this number of stress applications. Therefore, it may be possible to use the vibratory method of cavitation testing as an index of the approximate number of applications of stress required to break down the structure of any given material, and, hence, to show a relative fatigue value, to be used as a guide in predicting behavior of the metal in the regular fatigue-testing apparatus.

Appearance of Specimens

Each of the vibratory specimens had certain characteristics in common. The pitted area covered a diameter of $^3/_8$ to $^7/_{16}$ in. surrounded by an annular area which was unaffected by cavitation. High frequency of vibration probably concentrated cavitation in the smaller area, and the portion near the outside of the specimen had the action relieved by the surrounding liquid. The time interval between pressure and vacuum was evidently too short for the relief to travel more than $^1/_8$ in. With high-strength materials, the area was smaller in diameter and had the appearance of being sandblasted. With softer or weaker materials, the area affected was larger and the depth of pitting was greatest near the center. With the softest or weakest materials, such as plain cast iron, the depth of pitting was more uniform over the area but where nonuniform material was encountered, the pitting was deepest at the softer portions, and, in certain cases, narrow fissures extended into the outer area.

Photographs, magnified several times, are included of representative specimens in each class of material. The complete set of venturi specimens is shown for comparison. It will be noted that the deep-pitting stage had not yet been reached at the end of the test, usually not less than 50 hr. On the cast-iron specimens,

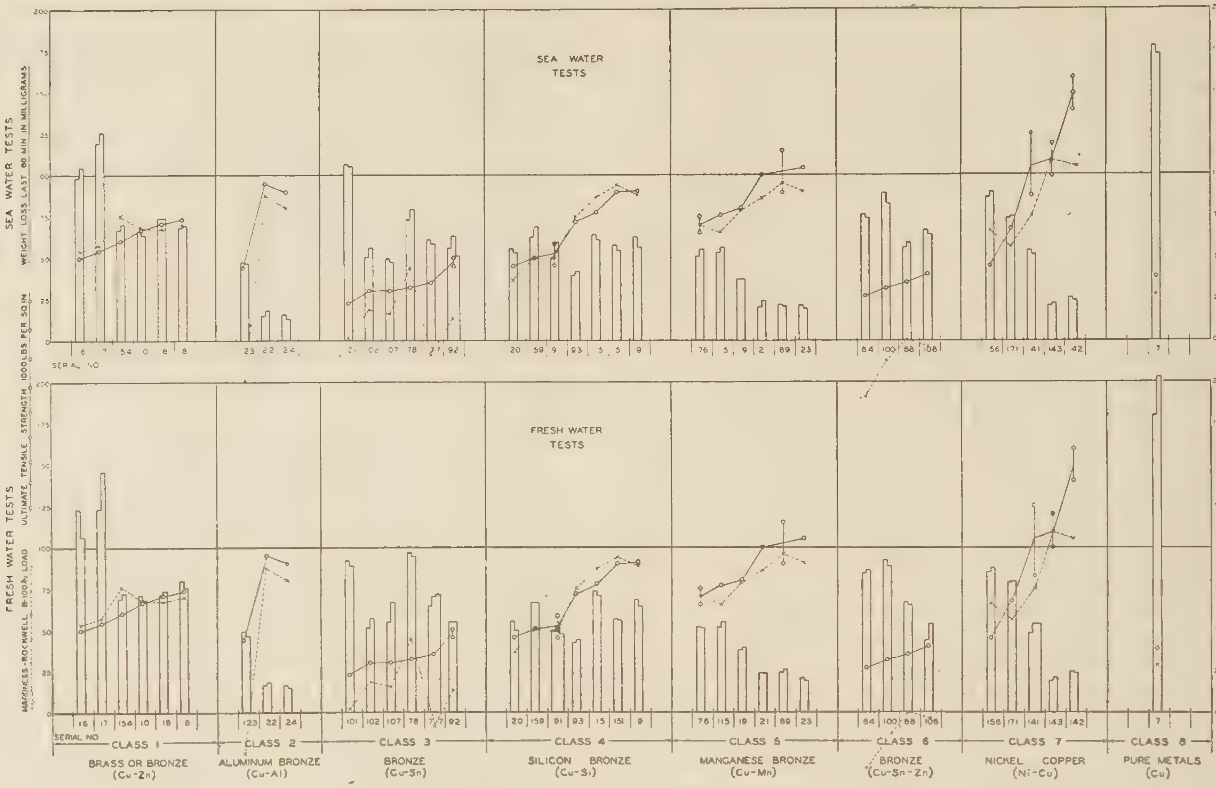

Fig. 7 Result of Tests of Nonferrous Materials

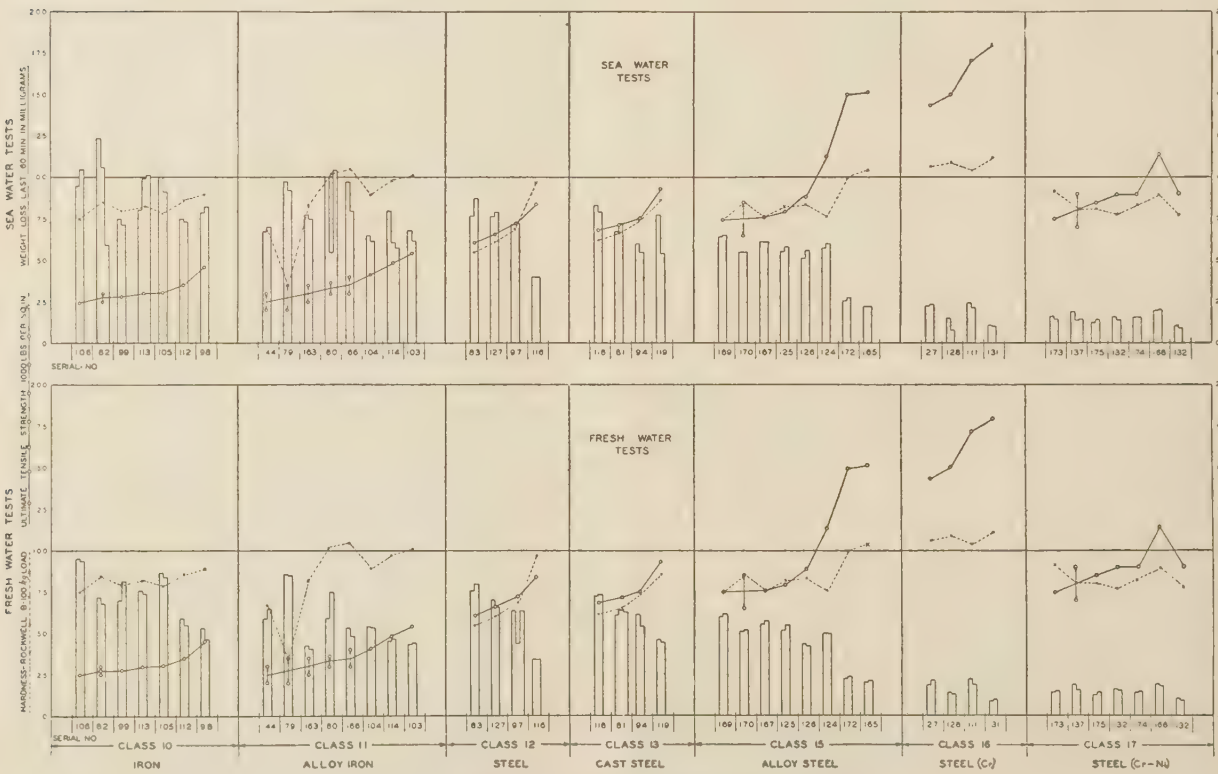

Fig. 8 Result of Tests of Ferrous Materials

evidence of corrosion on the venturi specimens was present with less pitting than is found on the vibratory specimens with an exposure period of only 90 min.

Results

The graphical representation of the results comprises two graphs, Fig. 7 for nonferrous and Fig. 8 for ferrous materials. Weight loss in the interval from 30 to 90 min has been plotted vertically for each specimen. Two or three specimens of each type of material are shown as a block with the upper end indicating small differences in weight loss for each specimen tested.

Results in fresh water are shown at the bottom of the sheet, and, immediately above them, are results of the tests in sea water. Ultimate tensile strength and hardness, based on the Rockwell B scale, have also been plotted for reference, and the different materials have been arranged from left to right in order of their tensile strength. Thus, the first material in any classification represents the type having lowest ultimate strength, whereas the material on the right is the one having highest ultimate strength.

Another method of illustrating relative resistance is by tabulating the materials according to weight losses for the two periods selected. Scale 1 for the 60 min following the initial half-hour period of exposure and scale 2 (the initial resistance to cavitation erosion), are shown in Figs. 9 and 10, respectively, the unit of milligrams per hour being used throughout.

Tables 2 and 3 give the *average* weight losses of each class for the uniform and initial scales, respectively, and form consolidated "relative scales" for nonferrous materials. Tables 4 and 5 give the same data for ferrous materials.

Performance by Classes

Each material, with individual compositions and distinguishing features, has been listed by classes in Table 1. Graphical summaries are inadequate to cover outstanding characteristics encountered in the tests. The behavior of each class of material will be described in detail, with the individual samples cited where their performance was unusual or distinct from others in the group.

Nonferrous Materials (Fig. 7)

Class 1, Brass or Bronze (Cu-Zn). This group comprises ordinary brass or bronze. Softer materials, having 85 to 90 per cent of copper and the remainder zinc, are lower in tensile strength. Remaining specimens have a composition of 60 per cent of copper and 40 per cent of zinc. High-copper alloys show much greater damage from cavitation than does 60–40 brass. There is little or no change in the performance in fresh water, as compared with sea water, and results of the four different 60–40 specimens show remarkably close agreement, having a cavitation damage between 70 and 75 mg per hr. These materials rank at the bottom of the average relative resistance scales for both cavitation erosion and for initial resistance to cavitation in either fresh or salt water.

Class 2, Aluminum Bronze (Cu-Al). In this group of aluminum bronzes, only three specimens were available for cavitation testing. Serial 123, having 92 per cent of copper and 8 per cent of aluminum has a lower ultimate strength than the ordinary brasses or bronzes in class 1 but shows appreciably less cavitation damage, being on the order of 50 mg per hr. The two high-strength bronzes, averaging 100,000 lb per sq in. ultimate, show about 15 mg per hr, and compare favorably with the best of the high-strength alloy steels in so far as erosion is concerned. This material shows little or no change in cavitation damage in fresh water, as compared with sea water, and stands at the top of the

Fig. 9 Relative Resistance Scale 1 (Uniform Erosion)

(Relative resistance based on weight loss between 30 to 90 min measurement.)

where 2 per cent of lead is included, and serial 78, where 5 per cent of lead is included. As before, high copper content apparently reduces ultimate strength and also reduces materially resistance to erosion. In the case of serial 101, which is an 86–14 alloy, the damage in fresh water is about 85 mg per hr, but, in sea water, this increases to 105 mg per hr. In contrast to this, the remaining materials in this classification either show no change between fresh and sea water or else indicate a reduction in cavitation damage, such as serial 78 for example, which decreases from 95 mg per hr in fresh water to 75 mg per hr in sea water. Some slight change is found in the performance of serial 77, which is a 90–10 alloy, the damage decreasing from 68 to about 60 mg per hr. In general, class 3 ranks sixth on the relative-resistance scales, but, due to less damage being suffered in salt water by all but serial 101, it is raised to fifth place on scale 1 for resistance to cavitation erosion for sea water. Its position remains sixth on scale 2 for initial resistance in either fresh or salt water.

Class 4, Silicon Bronze (Cu-Si). This group represents a wide range in chemical composition, but most samples have about 95 per cent of copper and from 2 to 5 per cent of silicon with certain other materials included in some cases. Average weight loss is about 50 mg per hr in either fresh or salt water but shows slightly less in sea water. It stands fourth on scale 1 for erosion in both fresh and salt water, but stands third on scale 2 for initial resistance, due to the greater skin effect than class 7. This material, together with class 5, is used widely in machinery and, in most cases, should prove satisfactory.

Class 5, Manganese Bronze (Cu-Mn). These materials have approximately the same chemical composition throughout but vary in ultimate tensile stress from 70,000 to 100,000 lb per sq in. Usual composition averages about 60 per cent of copper, about

FIG. 10 RELATIVE RESISTANCE SCALE 2 (INITIAL EROSION)
(Initial resistance based on weight loss for initial 30 min period.)

35 per cent of zinc and the remainder iron, manganese, or other materials in varying proportions. Some of these materials, namely, serials 21, 89, and 23, are extremely resistant to cavitation erosion, showing an average weight loss of only 20 mg per hr. Other types of manganese bronze, notably, serials 76 and 115, having lower strength, show an average weight loss of about 50 mg per hr in either fresh water or sea water. There is little or no change in weight loss between fresh and sea water with this material, and it is ranked second in all of the relative-resistance scales for nonferrous materials. Behavior under corrosive conditions has been found uncertain, and care must be used when the fluid is sea water.

Class 6, Bronze (Cu-Sn-Zn). This group comprises the more complex bronze alloys or the leaded bronzes. Serials 84 and 100 are the typical 85-5-5-5 bronze, whereas serial 88 is the standard composition G or Government bronze having 88 per cent of copper, 10 per cent of tin, and 2 per cent of zinc. Serial 108 has approximately the same composition, except that the tin has been reduced to 9 per cent, and the zinc increased to 3 per cent. All four materials have relatively low ultimate strength, and cavitation erosion in fresh water varies from approximately 50 to 85 mg per hr. In sea water, there is a measurable reduction in weight loss for all except serial 108 which shows an increase from about 50 to 65 mg per hr, even though this particular material has a higher ultimate strength that the other three. This group ranks fifth on the relative-resistance scale, except in sea water where it drops to sixth place due to the greater damage to serial 108. This material is easily worked and is readily machinable but does not appear to be as good for portions of the machinery exposed to cavitation as are several other of the classes.

Class 7, Nickel Copper (Ni-Cu). This group comprises alloys of nickel and copper in varying proportions, ranging from 30 per cent of nickel and 70 per cent of copper for serial 156 down to 66 per cent of nickel and 31 per cent of copper for serial 141.

Serial 171 falls about halfway between these two. It would appear that strength is increased materially as nickel content is increased, and cavitation damage is correspondingly reduced. Serial 156 averages about 85 mg per hr with the 30 per cent nickel content, whereas serial 141 loses only 60 mg per hr and has a 66 per cent nickel content. Serials 143 and 142 have approximately 63 per cent of nickel and slightly over 30 per cent of copper, but, in serial 143, about 3 per cent of silicon has been added, and, in serial 142, about 3 per cent of aluminum is present. Serial 142 has an extremely high ultimate tensile strength, ranging up to 150,000 lb per sq in., and its cavitation damage is represented by a weight loss of about 25 mg per hr in either fresh or salt water. Serial 143, however, has an ultimate tensile strength of about 110,000 lb per sq in. but has a cavitation-damage index of only 20 mg per hr as compared with 25 mg per hr for the higher-strength material. This group represents the widest variation in cavitation damage between individual materials and when averaged, falls in third place for resistance to erosion, scale 1, and in fourth place for initial resistance to cavitation damage, scale 2. If serials 142 and 143 alone were considered, they would fall in second place, whereas serials 156 and 171 would fall approximately in fifth place.

Class 8, Pure Metals (Cu). As a basis for comparison, specimens of pure copper were subjected to cavitation testing, and, in fresh water, this material loses about 185 mg per hr and in sea water, about 175 mg per hr. This has not been included in any relative-resistance scales as it was tested for general information only. It indicates that copper is relatively soft and has low fiber and fatigue strengths. When alloyed with very small quantities of silicon, tin, or other materials, the cavitation damage is reduced to one fourth that of the pure material.

Ferrous Materials (Fig. 8)

Class 10, Cast Iron. With ultimate tensile strength varying from 25,000 to 40,000 lb per sq in., cast iron is characterized by lack of uniformity and great increase in cavitation damage in sea water, as compared with fresh water. Maximum weight loss in fresh water is about 95 mg per hr, but this jumps to 115 mg per hr in sea water. Minimum damage is on the order of 50 mg per hr, but this, in turn, increases materially in sea water. In one case, serial 98, the material loses only 50 mg per hr in fresh water, but this increases to 80 mg per hr in sea water. It stands in seventh place on all scales of relative resistance.

Class 11, Alloy Iron. When iron is alloyed with nickel, silicon, or other materials, the strength is increased by a small amount, but the grain structure is greatly improved as cavitation damage is appreciably less than ordinary cast iron and, with few exceptions, the increase in weight loss between fresh and salt water is not as great as with ordinary cast iron.

Class 12, Steel. With rolled and forged steels of ordinary characteristics, without unusual alloying elements, tensile strengths varying from 60,000 up to 85,000 lb per sq in. can be obtained. With one exception, weight loss is between 50 and 75 mg per hr in fresh water but increases appreciably in sea water. This group stands sixth on relative-resistance scale 1 in fresh water and fifth in salt water. Initial resistance to cavitation, scale 2, is greater than cast steels or irons, in so far as fresh-water conditions are concerned, but it is less resistant than cast steel in salt water. Differences in composition between the various steels in class 12 are not very great, and the only distinguishing characteristic of serial 116 seems to be a higher percentage of manganese and a slightly greater carbon content, that is, 0.3 as compared with 0.25 per cent. Serial 83 has a still lower carbon content, 0.2 per cent, while serial 127 has the same carbon content as serial 116 but has no measurable percentage of manganese present. Slight differences in cavitation resistance may be due to varying carbon contents and to small changes in manganese content.

Class 13, Cast Steel. These cast steels are all of good quality having an ultimate tensile strength of 75,000 lb per sq in. They do not differ materially from the rolled steels of class 12 and follow the same general trend of having slightly greater damage in sea water, as compared with fresh water. In general, the characteristics of classes 12 and 13 are very similar, and they stand next to each other on the relative resistance scale, with cast steel showing slightly better resistance than rolled steel in sea water.

Class 15, Alloy Steel. In the alloy steel group, many different compositions are encountered all having less than 5 per cent of either nickel or chromium present. Serials 172 and 165 contain less than 5 per cent of nickel with about 1 per cent of chromium and have very high strength, namely, 150,000 lb per sq in., and show very little damage from cavitation. There is some slight increase from the average of 20 mg per hr loss in fresh water to 23 or 24 mg per hr loss in sea water for these two materials. The remainder of the alloy-steel group average close to 50 mg per hr loss in fresh water and slightly more than that in sea water. Performance of the other six specimens is remarkably uniform, and there are no distinguishing characteristics in either fresh or salt water. Alloy steel stands third on all relative-resistance scales and represents a very satisfactory material for turbine or pump impellers. It shows less cavitation damage than rolled or cast steel where alloying elements are not present.

Class 16, Chromium Steel. This classification includes chromium alloys having varying percentages of chromium in excess of 5 with a negligible percentage of nickel present. All four materials have approximately 12 per cent of chromium, and there are very few differences in their composition. Serial 131 was oil-hardened, whereas serial 128 was hardened by ordinary methods. Brinell hardness runs from 285 up to 375, and Rockwell B hardness is in the neighborhood of 105. Ultimate tensile strength of serial 131, reaches 180,000 lb per sq in., and this particular material is the most resistant to cavitation erosion, scale 1, of any tested, but its initial resistance, scale 2, is not as high as some of the nickel-chromium steels in class 17. On all relative-resistance scales, this material stands second, based upon the average of materials tested. It shows somewhat increased damage in sea water, as compared to fresh water, with a possible exception of serial 128.

Class 17, Nickel-Chromium Steel (Cr-Ni). Nickel-chromium steels represent variations of the so-called stainless steels and are uniformly very resistant to cavitation damage. The maximum rate is on the order of 20 mg per hr and the average, in either fresh or salt water, is slightly under 18 mg per hr. This material stands at the top of all relative-resistance scales, both for uniform erosion, scale 1 and for initial resistance to cavitation damage, scale 2. Ultimate tensile strength varies from 75,000 lb per sq in. to a value in excess of 115,000 lb per sq in. but, for the most part, ranges between 75,000 and 85,000 lb per sq in. The alloy has a dense grain structure and high fiber stress and fatigue limit. The experience record with this material in acutal service in fresh water indicates that it is most satisfactory. It has been found possible to apply a welded coating of nickel-chromium steel to ordinary steel-turbine or pump blades to make them more resistant to cavitation damage. Use of this material in contact with ordinary steel in sea water produces severe electrolytic action and is not recommended for welded coatings. General use of this material in sea water is still open to question as results show in some cases that severe local corrosion has developed rapidly after submergence in sea water. This unsatisfactory performance in sea water has stimulated research work, and improvements in corrosion resistance have been made by changing the chemical composition and by the use of other alloying elements. Before

being used in sea water, special service tests should be made under conditions closely approaching actual operation.

Venturi Tests

As mentioned previously, the original method developed for testing resistance of materials to cavitation was in a venturi-shaped section through which water was passed at an extremely high velocity. To coordinate previous research work with the new vibratory method, the original contract with Massachusetts Institute of Technology contemplated checking six different materials, one specimen in fresh water and two specimens in salt water, to determine whether or not the relative scale of resistance to cavitation would be the same if established by the vibratory method as compared to its development by the venturi method. As the vibratory tests proceeded and the results indicated that the scale of relative resistance was reliable and, also, since the funds available for this investigation were restricted due to the termination of the project, only three materials were tested by the venturi method, and the funds thus released would be utilized for additional tests by the vibratory method. The small venturi machine at the Massachusetts Institute of Technology was to be employed for these tests, and sufficient quantities of sea water from Cobscook Bay shipped to Cambridge for this purpose.

Careful study of the behavior of the smaller venturi apparatus indicated that its use would require a much longer time for the investigation than was available, but, if the larger venturi machine was employed, the time element could be reduced greatly, and special castings or rolled plates needed for the smaller apparatus would become unnecessary. There was sufficient material remaining from the vibratory tests to prepare duplicate specimens for the large venturi tests. This represented a distinct advantage in that identical materials were investigated in both types of apparatus.

The venturi specimen consisted of a flat disk, $1^1/_4$ in. in diameter and approximately $^1/_4$ in. thick, which was fastened by three screws to a holder inserted in the throat of the venturi apparatus. These specimens were prepared in the laboratory machine shop and were polished to give the same surface conditions as with the vibratory apparatus.

Three materials were selected; namely, cast iron, class 10, serial 82; cast steel, class 13, serial 118; and manganese bronze, class 5, serial 76; after a careful study of their behavior in sea water in the corrosion laboratory at Eastport. They occupied widely separated positions on the scale of relative resistance and, at the same time, were materials that were frequently employed for hydraulic-turbine runners and pump impellers. A supplementary test covering the behavior of nickel-chromium steel, class 17, serial 132, was conducted in fresh water only.

Artificial Sea Water

The quantity of water required for tests in the large venturi apparatus was very large, approximately 5 tons, and precluded the idea of utilizing water taken from Cobscook Bay. During the investigations, various synthetic sea-water solutions were prepared and tested in comparison with natural sea water and ordinary fresh water. A special solution, used in the venturi-test program, simulated very closely the water taken from Cobscook Bay.

It was found that Turk's Island salt was available in Eastport, and a large sample was obtained for test purposes. This salt is prepared from sea water by evaporation and approximates closely the chemical composition of the salt in natural sea water but is deficient in a few constituents. The chemists in the Concrete Laboratory prepared a synthetic sea water based upon the use of Turk's Island salt to give a solution having the same density as natural sea water; namely, 1.023. This Turk's Island sea water gave less damage in the vibratory apparatus than did the natural sea water drawn from Cobscook Bay. Several variations of chlorine content were tried, and the final solution was prepared with the following percentages of the various types of salt:

	Per cent
Turk's Island salt	53.6
Sodium chloride	32.5
Magnesium chloride	7.13
Magnesium sulphate	5.7
Calcium chloride	1.07

The density of this solution was 1.0237 as compared with 1.023 for natural sea water.

To correlate the two methods more carefully, samples of the artificial sea water were withdrawn from the venturi apparatus during the test, and additional vibratory tests made on the same materials in this artificial sea water to check the behavior against the previous vibratory investigation in natural sea water (Fig. 5). The solution causes about the same damage as does natural sea water, except in the case of cast iron where some decrease in the damage was found. In general, the artificial sea water can be considered the test equivalent of natural sea water and the results obtained in the venturi apparatus utilized without danger of incurring any serious error.

Comparison Between Venturi and Vibratory Methods

The venturi method had been used previously in determination of the relative resistance of different materials to cavitation erosion. Attempts have also been made with some degree of success to correlate the data obtained from different venturi-testing units. It has been found that the form of profile, size of unit, air content and temperature of the fluid, velocity of flow, and absolute pressure at the venturi throat have a direct bearing upon the amount of cavitation damage occurring on the test specimens.

With the vibratory apparatus, however, no such basis of previous experience is available. Except for the check tests on cast iron, cast steel, and bronze in the venturi apparatus at Massachusetts Institute of Technology, no comparison between the two methods has been made.

Comparison of weight loss on the various materials tested by the vibratory method with weight loss on the same materials tested by the venturi apparatus indicated immediately that the two series of investigations cannot be compared directly unless some other factor, such as time or frequency of vibration, is considered. Detailed study of results by the two methods was made in an endeavor to correlate them in some reasonable manner.

Comparison of Weight Loss per Unit Area

The first step in securing this comparison was to reduce all readings of weight loss to a common basis of weight loss per unit area. The range between maximum and minimum curves in the venturi apparatus was much greater than in the vibratory apparatus. It was found that weight loss per unit area per unit time showed the same discrepancies, and the ratio between the values in the two types of equipment showed that rate of weight loss per hour in the vibratory apparatus was about 45 times that in the venturi apparatus. This was about one third the ratio of the frequencies.

Frequency of the vibratory apparatus was 6690 cycles per sec. Calculated frequency of the venturi apparatus was 47 cycles per sec, and measurements made in the venturi tests confirmed this value as being in the neighborhood of 50 cycles per sec. The ratio between the two frequencies is about 140 which would indicate that the vibratory apparatus would produce the same

number of cavitation blows in $^1/_{140}$ of the time required in the venturi apparatus.

A new unit of measurement, "weight loss per unit area per million blows," was then used and designated as W. These values still showed a marked discrepancy between the two methods, but, if the damage W at the end of a given number of blows is compared for the same material in the two different types of tests, still another ratio, S, called for convenience "the relative-intensity ratio," is possible.

While this ratio S varies with different types of materials, due probably to the differential existing between the ultimate

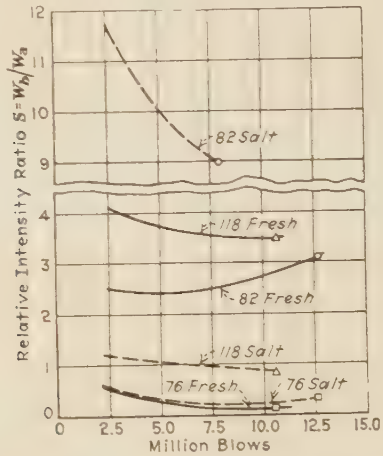

FIG. 11 RELATION BETWEEN VIBRATORY AND VENTURI RESULTS

strengths of the materials and the stress imposed by the cavitation blow, there was a marked uniformity for a given material. As shown in Fig. 11, the ratio S remains practically constant for the range up to between 10,000,000 and 12,000,000 blows, with the exception of the cast-iron specimen in salt water. Severe corrosion on the venturi test may account for this.

Investigation was also made comparing rates of change of cavitation damage, which would be indicated as R, being the ratio of the incremental weight losses obtained as the first differential of the weight-loss curves. This study showed no major departure from results secured by use of the relative-intensity ratio S.

Relation Between Vibratory and Venturi Methods

It will be seen that a direct relation between the two methods is not possible from the meager test data now available from the venturi tests of the three materials investigated. It is gratifying to note, however, that, in both vibratory and venturi tests, the relative positions of the different materials are the same with respect to each other, bronze being the most resistant, steel second, and cast iron third. The relative-resistance rates (Table 6) are compared with cast iron in fresh water.

TABLE 6 COMPARISON OF RELATIVE RESISTANCE BY VIBRATORY AND VENTURI METHODS

		Vibratory		Venturi	
	Material	Fresh water	Sea water	Fresh water	Sea water
76	Bronze	1.6	1.5	60.0	55.0
118	Cast steel	1.2	0.95	1.6	5.6
82	Cast iron	1.0	0.54	1.0	0.2

Appearance of the individual specimens indicates that the action in the venturi apparatus is proceeding at a much slower rate than is the case with the vibratory testing. In the venturi tests, the bronze and stainless-steel specimens give the appearance of severe hammering having taken place on the surface. As the test continued, these surfaces gradually assumed a pitted appearance. At the end of 60 or 80 hr, a pronounced change in the surface could be detected, and numerous pits were present. This is equally true of stainless steel, serial 132, except that the pits were few in number and relatively small in size.

In the case of cast iron, which is brittle and not ductile, the initial stage is practically nonexistent, and pitting action begins at once. With cast steel, some plastic deformation takes place in initial stages of exposure to cavitation action, but the metal did not retain its fiber strength for as long a period as certain nonferrous materials.

Combined with the action of cavitation damage, there was also the corrosive action of sea water, which, in the venturi apparatus, apparently increased the damage due to longer exposure of the specimen to sea water, permitting the chemical action to become further advanced. This is particularly noticeable with respect to serial 82, cast iron, in sea water as compared with fresh water.

Plastic Deformation and Pitting

Considering only cavitation action independent of corrosive action, it would appear that work hardening or plastic deformation takes place on those materials which are ductile. The second action, indicated as pitting, apparently takes place only after the fatigue limit or ultimate strength of the fibers has been reached.

It is probable that the intensity of the blow in the vibratory apparatus is greater than is found in the venturi apparatus with the result that the work-hardening and plastic-flow period may be passed in a relatively few minutes, and, in some cases, the blow intensity is so great that the ultimate strength of the fibers is exceeded at once, in which case the pitting stage is reached immediately.

Conclusions

(1) The conclusions to be drawn from this investigation must be qualified by considering the behavior of the various materials in sea water in the first two phases of the corrosion investigation, namely, pure corrosion and electrolysis. Many high-strength materials have not indicated satisfactory behavior in sea water at Eastport.

(2) In so far as application to hydraulic turbines, pumps, and other machinery operating in fresh water under conditions where cavitation will exist, various materials can be selected with reasonable assurance from the scale of relative resistance developed for fresh water. The consolidated-resistance scale for both cavitation erosion and initial resistance to cavitation can be found in Figs. 9 and 10, where individual materials are listed in the order of their loss of weight in the vibratory apparatus.

(3) Where equipment is to be operated in salt water or in contaminated water which would have a corrosive action, or where material is subjected to electrolysis due to its being in contact with some dissimilar material, the cavitation-resistance scales alone are not reliable, and it is necessary to have the comparative data upon the corrosion and electrolysis behavior of the materials in the particular fluid under consideration.

(4) From a comparison of results of the venturi tests with the vibratory tests, it is evident that the same relative behavior is found in the two methods. However, the vibratory test represents a much accelerated condition, and the 90-min test period offers little time for chemical action to become effective. The venturi method allows more time for chemical reactions to take place, and the greater damage to cast iron in salt water is probably due to the chemical action assuming substantial proportions as compared with pure cavitation erosion. Actual service conditions may produce greater relative damage in sea water than was

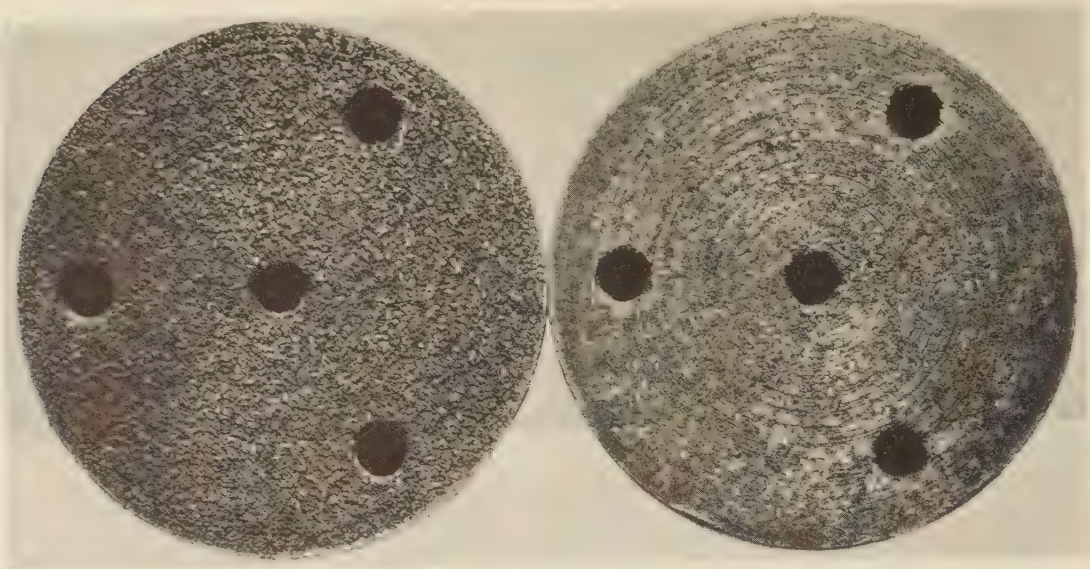
indicated by vibratory tests, particularly with regard to ferrous materials.

(5) Analysis of an independent set of tests previously made in a venturi apparatus for one of the organizations supplying material for this program indicated that the same relative-resistance scale as developed by the vibratory apparatus holds approximately true with the venturi apparatus and, hence, relative performance of the two sets of apparatus can be relied upon to give reasonably satisfactory results.

(6) Comparison between natural sea water and artificial sea water as shown in Fig. 5 indicates that synthetic water in the venturi apparatus caused slightly less proportional damage in the case of cast iron than did natural sea water, whereas it caused slightly more damage with the cast-steel specimens. In all three cases, water drawn from the venturi apparatus and used in vibratory tests at 34 C show slightly more damage than in fresh-water tests at 25 C. By comparison, therefore, it would appear that cast iron as tested with synthetic sea water would not show as much damage as with natural Quoddy water. In the venturi apparatus, a slightly greater differential between fresh and sea water would have been found if it had been possible to use natural instead of artificial sea water. The discrepancies are not sufficient to change the conclusions or to change the scale of relative resistance.

(7) Recommendations in regard to the specific materials to use in turbines, pumps, and other similar equipment are beyond the scope of this paper. In cases where fresh and noncorrosive water is available, such as exists in the majority of water-works pumping plants or in almost all hydroelectric plants, the scale of relative resistance (Fig. 10) determined for fresh water should be a reasonably accurate guide to the selection of proper materials. If a cheaper material can be coated with a more resistant metal by welding or other means, then the coating metal can be selected in the same manner.



Fresh water

(8) Where a corrosive fluid is encountered, be it sea water in its various conditions of purity or contamination, or some alkaline or acid water, or a corrosive solution in a chemical plant, the proper material can be selected only after a series of corrosion tests under actual conditions or from a long and comprehensive set of experience records. Too much emphasis cannot be placed upon the rapid deterioration of structures and equipment exposed to corrosion or electrolysis. The method of protecting cast-steel turbine runners with a local coating of nickel-chromium or other corrosion-resistant steel cannot be used where sea water is present due to the severe electrolytic action that takes place between these two materials.

Acknowledgments

The Passamaquoddy Tidal Power Project was carried on by the Corps of Engineers of the U. S. Army. Lieut.-Col. Philip B. Fleming was district engineer at Eastport, Me., and Capt. Hugh J. Casey was in charge of engineering design, assisted by Paul F. Kruse, head engineer.

The materials-corrosion investigation was instituted by the writer as senior mechanical engineer, assisted by Edward Hutchins, associate engineer. Harold A. Scott was resident engineer for the Eastport district at the Massachusetts Institute of Technology during the conduct of the tests. Particular credit should be accorded to Dr. J. C. Hunsaker, head of the mechanical-engineering department, and Dr. H. Peters, professor of hydraulics and aerodynamics at Massachusetts Institute of Technology, in working out the details of this new method of test and for their courage in accepting a contract to perform such a comprehensive series of tests under conditions that represented so radical a departure from accepted practice. Their assistants should be commended for their spirit of cooperation and for carrying out the actual test work in a highly satisfactory manner.

The writer is personally indebted to the executives of the Eastport district for official permission to publish the results of this most interesting problem in research.

The conclusions expressed herein are the writer's individual opinions and should not be considered as official statements of the U. S. Engineer Department.

Pitting Resistance of Metals Under Cavitation Conditions

By J. M. MOUSSON,[1] BALTIMORE, MD.

The paper describes the experimental apparatus and testing procedures used to determine the pitting resistance of metallic materials under accelerated cavitation conditions. The results of this research, sponsored by the Safe Harbor Water Power Corporation, are compiled in a series of tables and the classification of metals is discussed in the light of the metallurgical data made available for the materials and the metallographic analysis carried out in connection with the research program. The conclusion is reached that a more rational approach has been provided for selecting materials subject to attack by cavitation.

Introduction

THE PROPER selection of materials for hydraulic equipment exposed to cavitation is still exceedingly difficult in many instances in spite of the fact that pitting has been discussed rather frequently in the past. It has been generally recognized that the main obstacles to a more rational approach were the absence of truly comparative data on the pitting resistance of an adequate number of materials, which may be given consideration in the course of manufacture and maintenance of hydraulic machinery, and the lack of definite information regarding those alloy characteristics influencing the resistance of materials, as well as the nature of their failure when exposed to the punishment under consideration.

Recognizing the need for further progress, the Safe Harbor Water Power Corporation decided in 1934 to sponsor a research program with the following objectives:

(a) To make a standard loss determination on a large variety of metals in cast, rolled, forged, welded, and sprayed conditions, when exposed to cavitation artificially produced by a testing apparatus.

(b) To study the nature of the failure and to determine, if possible, those material characteristics, controllable or uncontrollable, influencing the resistance of the materials.

(c) To compare pitting due to cavitation, and erosion due to water jet, to see whether or not the results obtained with the cavitation test stand can be used as a basis for selecting materials to withstand both types of stress application.

Cavitation Apparatus

With the test stand as shown in Fig. 1, a zone of cavitation was produced by means of a double weir arrangement. This general type of design, originally developed by Walchner, found practical application for the tests carried out by Schröter at the Walchensee development (1).[2] Its advantages over venturi profiles, or sections with protruding obstructions were the rather limited expanse of the cavitation zone, and the accelerated pitting conditions, two factors particularly desirable with a view to the size of the specimens and the duration of the test runs, respectively. In addition to some minor changes in the weir shapes and orifice dimensions, a major modification was made in the location of the specimens. In the original design by Walchner a single specimen was placed opposite the guiding weir, while the apparatus finally adopted for these tests provided for two specimens inserted in the parallel side walls opposite each other. This permitted the testing of duplicate specimens simultaneously, and gave a higher degree of test accuracy without increasing the number of runs. The new location for the specimens was also desirable because pitting was found to be far more severe on the side walls than at the bottom opposite the guiding weir. At the same time there could be no doubt that, at the new location the specimen was less subject to the direct impingement of the fluid which produces impact stresses superimposed on those exerted by cavitation. The dimensions of the specimens were $4 \times 1^1/_4 \times {}^1/_4$ in. (Fig. 2).

To accelerate the test conditions sufficiently a high head had to be provided, and the apparatus was therefore installed at the Holtwood Steam Station of the Pennsylvania Water & Power Co., where a maximum head of 1250 ft could be made available by using a raw-water pump and a boiler feed pump in series.

For ordinary testing, fresh raw water from the forebay of the Holtwood Hydro Station was supplied continuously to the test stand and wasted into the tailrace. For special purposes, however, a recirculating system was installed. The pressure upstream and downstream of the test stand could be regulated by the speed of the boiler feed pump and by a valve, respectively. Based on the results of the calibration runs shown in Fig. 3, standard testing procedures were adopted using a head pressure of 480 lb per sq in. and a back pressure of 25 lb per sq in. The duration of each run was 16 hr. The amount of pitting was determined by weighing the specimens before and after the test. For comparative purposes, however, the loss in volume was used to compensate for the difference in specific gravity of the various materials.

The influences of variation in water temperature and air content were also investigated. As may be seen from Fig. 4, the losses obtained at various temperatures of the available seasonal range, with specimens of rolled, stainless, 18-8 chromium-nickel steel of a particular analysis, were not constant but, for all practical purposes, directly proportional to the vapor pressure. This characteristic was confirmed by tests carried out with the recirculating system where the temperature could be controlled artificially. Under the same conditions, repeat tests were made using boiler-plate steel, sheet brass, rolled-copper bus bar, and three different types of welding deposits, in which the same characteristic was indicated. Because of the temperature effect all

[1] Hydraulic Engineer, Safe Harbor Water Power Corporation. Mem. A.S.M.E. The author was graduated in 1926 from the Swiss Federal Institute of Technology, Zurich, Switzerland. He was designing engineer with the Pennsylvania Water & Power Company and the Electric Bond and Share Company in 1928 and 1929. Since that time he has served on the engineering staff of the Safe Harbor Water Power Corporation as designing, sponsor, and hydraulic engineer.

Contributed by the Hydraulic Division and presented at the Joint Meeting of the Hydraulic and Applied Mechanics Divisions of The American Society of Mechanical Engineers, at Cornell University, Ithaca, New York, June 25–26, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

losses were corrected by an amount based on the ratio of the vapor pressures at test temperature and at a common temperature arbitrarily assumed to be 20 C.

As may be seen from Fig. 5, the tests with artificial air injection indicated that with a head pressure of 480 lb per sq in. (throat velocity 265 fps) more than one per cent of air was required above the natural air content of the water to produce a cushioning effect of sufficient magnitude to reduce pitting by an appreciable amount. Since the natural air-content variations could be expected to be less than one per cent no correction needed to be applied to compensate for this seasonal effect under the testing conditions adopted.

Results of Research

A *Metallurgical Aspects of Failure Due to Cavitation*

Prior to this research, it had already been recognized that failure caused by cavitation was primarily mechanical. At the same time three different theories had been developed relating the pitting resistance either to the corrosion-fatigue limit (2), the Brinell hardness (1), or to the tensile strength (3), but inconsistencies left the field wide open to speculation.

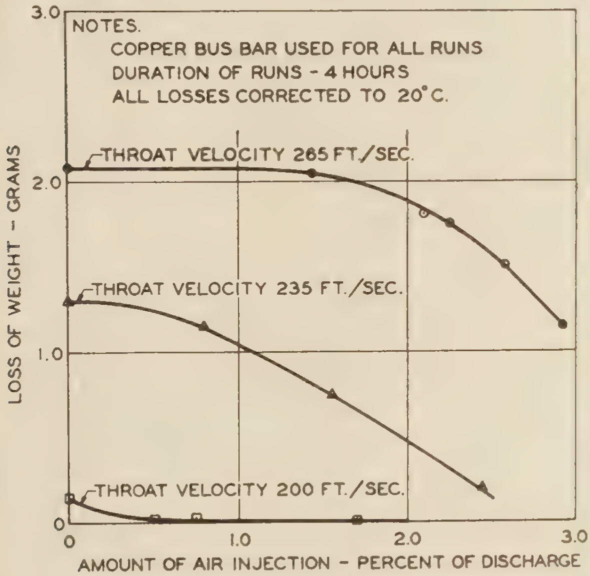

Fig. 5 Effect of Air Content on Pitting

Based on the photomicrographic analysis of many specimens in the course of this investigation, it may be concluded that with regard to the mechanical failure, the following alloy characteristics are of influence: Yield point, capacity of deformation or yield absorption, tensile strength, fatigue properties, original hardness, cold working qualities or susceptibility to strain hardening, grain size, grain boundaries, grain shape, grain structure, distribution of alloy constituents, chemical composition, impurities, and crystallographic properties. Although one or another of the above characteristics may be predominant with regard to the resistance of one particular material, nevertheless it should be borne in mind that all other characteristics contribute their share in any case and are of vital importance particularly when the individual influences are combined to a composite effect.

Some pertinent facts pertaining to the metallographic phase of this research have been published previously (4, 5). It may suffice to say that two types of failure were indicated:

(*a*) Failure due to successive deformations in the zone of highest stress concentration after the capacity of yield has been exhausted (Fig. 6).

(*b*) Failure due to fatigue beneath the zone of possible yield where some stress distribution has already taken place. The separations in this zone may be typical fatigue or cleavage cracks (Fig. 7).

The relationship of yield point, capacity of deformation, and fatigue limit differ in various materials and, depending upon these, as well as upon the severity of cavitation, one or another type of failure may predominate. Yield point, capacity of deformation, tensile strength, and fatigue limit may be termed primary influences as these physicals have direct bearing upon the nature of the failure. All other alloy characteristics referred to above may be termed secondary, not with regard to their importance, but because they do not change the nature of the failure. The importance of the secondary influences can best

ture. Specimens nos. 1 to 4 have basically a ferritic type of grain structure while specimens nos. 5 to 7 show an austenitic matrix. It can readily be seen that for each individual group the effect of the hardness is clearly indicated as the cavitation loss decreases consistently with increasing hardness. However, comparing the losses of both groups with each other the influence of hardness appears to be overshadowed by a characteristic originating in the grain structure. An austenitic matrix, in which various constituents form a solid solution, appears definitely superior to one of the ferritic type, consisting of separate complexes of elements or combinations of elements. The reason for this phenomenon lies in the excellent cold working properties of the austenite.

Comparing the results obtained on irons with those on plain and alloyed steels in Table 2, it becomes evident that the losses of the former group were comparatively large. The reason may be attributed to the free carbon content of the irons, present in the form of flakes. Keeping in mind the nature of the punish-

ment as best defined by implosions in rapid succession, high stress concentrations are likely to occur in the vicinity of flake tips. It is obvious that the number and the size of these flakes may influence the pitting resistance. This may best be illustrated by specimen no. 5, Table 1, showing an unusually high loss in comparison to specimens nos. 6 and 7 in spite of its austenitic matrix. Ordinarily, fine distribution of the free carbon content may be observed in these nickel-copper cast irons, that is, a large number of flakes of small size. The photomicrographic analysis disclosed that this specimen contained fewer flakes of

unusually large proportions which facilitated separation along the boundaries of the flakes.

In view of the fact that, in the iron group, the strain-hardening effect is superimposed by the influence of the carbon distribution, it may be well to check this phenomenon on cast and rolled stainless steels. For instance in Table 5, specimens nos. 64 and 81 show a very large difference in pitting resistance. Although the original hardness and the yield point of the austenitic, stainless, 18-8 chromium-nickel steel were lower than that of the stainless 17 per cent chromium steel, the pitting resistance of

a: Actual Analysis e: Estimated Analysis • Maximum

showing cast nonferrous alloys, it may be observed that specimens nos. 135 and 146 show decidedly different losses in spite of the fact that the Brinell hardness and the yield point are of the same magnitude. At the same time Rockwell-hardness tests in the zone of attack showed only minor differences in the susceptibility to strain hardening for the two alloys. The only real difference was disclosed by the photomicrographic analysis which showed the grain size of specimen no. 135 to be appreciably smaller than that of no. 146. This seems to indicate that the resistance to cavitation increases with decreasing grain size.

The above characteristic is not surprising as the failure in most cases was found to be transcrystalline. From the metallographic studies, it was apparent that the progress of fatigue cracks was retarded temporarily by the grain boundaries. The more grain boundaries encountered, the more difficult it is for a crack to make headway. This phenomenon may be true, not only with respect to the fatigue cracks, but also for those separations taking place in the zone of plastic deformation after the capacity to yield has been exhausted.

From the data given in Tables 2, 5, and 6, it is the former alloy is far superior. All other austenitic stainless steels listed in Tables 5 and 6, show the same tendency whether they are of the 18-8, 24-12, or 26-13 chromium-nickel variety.

There can be but little doubt that strain hardening is of far-reaching importance, nevertheless its beneficial effect may not necessarily overshadow the influence of the original hardness. This is substantiated by a comparison of the losses and the physicals of specimens nos. 108 to 112, inclusive, in Table 6.

In addition to the influence of surface hardening noticeable not only on austenitic materials referred to above but also on many other alloys not particularly susceptible thereto the grain size appears to be of far-reaching importance. From Table 8

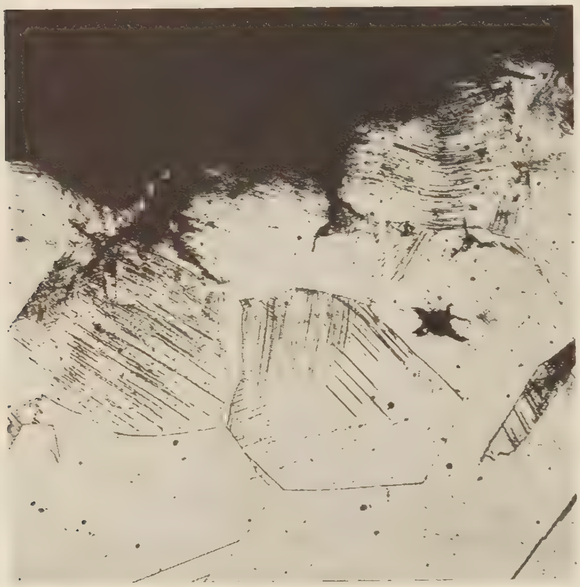

FIG. 8 COARSE GRAINED, STAINLESS, 18–8 CHROMIUM-NICKEL STEEL. NOTE SLIP BANDS AND FATIGUE CRACKS (Specimen No. 109, Table 6. ×100.)

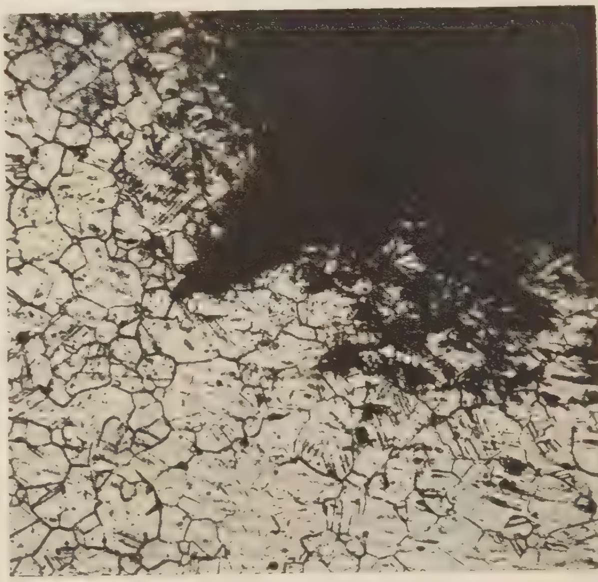

FIG. 9 FINE GRAINED, STAINLESS, 18–8 CHROMIUM-NICKEL STEEL (Specimen No. 110, Table 6. ×200.)

also evident that heat-treatment has a decided effect. This is to be expected as treatment affects both the physicals and the grain size. Its effect can best be shown by keeping the chemical composition constant and varying the treatment. What may be accomplished even with low-alloy steels is indicated by the high resistances obtained with the chromium-molybdenum steel series, Table 2, specimens nos. 22 to 24. A somewhat larger range of losses was observed by the treated, rolled, stainless, 12 per cent chromium-steel specimens nos. 90 to 93 in Table 6. In the same table another typical example is the rolled, stainless 18-8 chromium-nickel specimens nos. 109 and 110. Figs. 8 and 9.

Generally speaking, the results indicated that rolling and forging are advantageous, and often superior to casting, as higher

physicals can be obtained. Rolling and forging may, however, be detrimental in cases where a well-defined stratification is produced which is conducive to separation along parallel grain layers. Photomicrographic analysis showed that a weakness from this source becomes particularly apparent where, due to the processing and heat-treatment, a laminated structure is obtained consisting of large grains. This phenomenon was found to be of minor or no importance with greatly refined grain structures where more interlocking is provided.

Not only are differences to be expected in specimens produced by the various manufacturing procedures such as casting, rolling, and forging, but the way a particular method is carried out may contribute in some measure to the pitting resistance. For example, in casting, the rate of cooling may be varied. Heat may be dissipated more rapidly in chilling the molten metal in a cast-iron mold than in sand. The more rapid cooling is less conducive to grain growth in the material and therefore the higher may be the resistance to cavitation. This is borne out by a comparison of specimen no. 70 with 71 in Table 5, no. 138 with 139, and 141 with 142 in Table 8.

The size of the grain can also be influenced by means of alloying elements such as vanadium and molybdenum. This may be demonstrated by the results of three groups consisting of three specimens each listed in Table 5, nos. 60 to 62, nos. 67 to 69, and nos. 76 to 78. For all three groups, which are stainless, 12 per cent chromium steels, the heat-treatments were identical. A comparison between the first and third group shows the beneficial influence of molybdenum, while the higher physicals obtained with nickel as an alloying element in the second group also produced increased resistance.

The effect of nickel additions can be further demonstrated by a comparison of the results obtained with specimens nos. 70 and 72 to 75. Here the successive increases in nickel content reduced the losses step by step. It may be mentioned that the grain structure of this entire series was exceedingly coarse which explains the relatively large losses shown with the lower percentages of nickel in spite of the hardness. This fact is another typical example showing that grain size is of utmost importance and that it should not be neglected even when considering high-alloy steels.

Minor changes in the chemical composition can influence the resistance adversely. Comparing, for instance, the loss of specimen no. 90 with that of no. 97 in Table 6, it will be noticed that the latter specimen suffered considerably more in spite of the greater hardness. This apparent discrepancy is caused by the addition of sulphur in alloy no. 97 to produce a stainless steel of free-machining qualities. The photomicrographic analysis disclosed that sulphur is present in the form of flakes or streaks, producing stress concentrations and facilitating separation along their flanks. At the same time it may be realized that impurities or nonmetallic inclusions, and sulphur in this case may be regarded as an impurity, are detrimental because they are often the nuclei of fatigue cracks and also facilitate their progress. A similar phenomenon is responsible for the comparatively large losses obtained with the forged, stainless, 14 per cent and 17 per cent chromium steels listed in Table 7. Here the carbide-ridge areas seemed to permit quick development and rapid progress of fatigue cracks.

(*b*) *Surface-Treated Materials.* From Table 10 it is apparent that the protection afforded by surface treating depends upon the depth to which the treatment penetrates as well as upon the nature of the skin itself. The large losses obtained with the chapmanized and nitrided materials are due to the shallowness and brittleness of the skins. The penetration with chapmanizing was deeper than that with nitriding which had a decided effect upon the resistance. The large loss with the aluminite finish is not surprising because the skin produced was only 0.001 in. thick so that even the Rockwell tests did not give a true indication of the real surface hardness.

The results with the cloudburst-hardened materials are of interest. Due to the fact that cold working increases the fatigue limit in the strain-hardened zone, this type of treatment has particular merits. This is especially true in cases where machining is required, necessitating reasonably low original physicals, and where subsequent heat-treatment may not be advisable due to possible warpage. It may be noted that a definite maximum in surface hardness can be reached for each material.

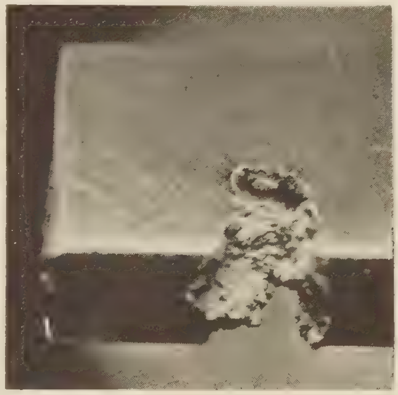

FIG. 10 TYPICAL WATER-JET SPECIMEN
(P.M.G. metal. ×5.)

Carrying the treatment too far, that is, exhausting the capacity of strain hardening, decreases the surface hardness and shows a corresponding increase in loss.

(*c*) *Welded and Sprayed Materials.* In analyzing the results obtained with welding deposits, Tables 11 to 14, various factors must be borne in mind. First, the compositions given refer to the wires and not to the deposits. In the course of welding some percentages of alloying elements may be lost. For instance, the reduction in chromium content of the stainless chromium or chromium-nickel steels may be as much as one per cent. Second, the chemical composition is influenced by the type of coating used. Third, there is an effect from the base metal. That the base as well as the number of welded layers has an influence is demonstrated by specimens nos. 190 to 194, nos. 197 and 198 in Table 12, nos. 223 and 224, and nos. 227 and 228 in Table 13.

Regarding the results in general, the stainless chromium steels showed the best average resistance. Some of the relatively high losses of various austenitic stainless-steel welding deposits of the chromium-nickel variety may be explained to some extent by the improper proportioning of the chromium and nickel contents. The strain-hardening characteristics appear to be rather sensitive to slight changes in the chemical composition. Keeping in mind a possible loss of alloying percentages in the course of welding, too much nickel or not enough chromium in the deposit may impair these characteristics decidedly. For this reason molybdenum may be added to good advantage. A second method of increasing the resistance is demonstrated by specimen no. 241. Here an increased original hardness and a greater susceptibility to strain hardening were obtained by lowering both the chromium and the nickel contents from the usual 18–8 proportioning of chromium and nickel in this variety of steels.

Comparing the losses obtained on welded and sprayed deposits of materials similar in chemical composition, it becomes apparent that welding produces structures of far better resist-

ance. Although spraying may have advantages in many other types of maintenance, the results as presented in Table 15 warrant the conclusion that spraying can be recommended only for temporary repairs or very mild cavitation conditions.

C Pitting Resistance of Materials Exposed to Water Jet

A representative number of specimens consisting of materials identical with some of those exposed to cavitation were prepared for determination of loss due to water jet. These tests were carried out at the East Pittsburgh laboratory of the Westinghouse Electric and Manufacturing Company. The testing apparatus, described in detail elsewhere (6, 7), consists of a 12-in. diameter disk rotating at high speed. Two specimens like that

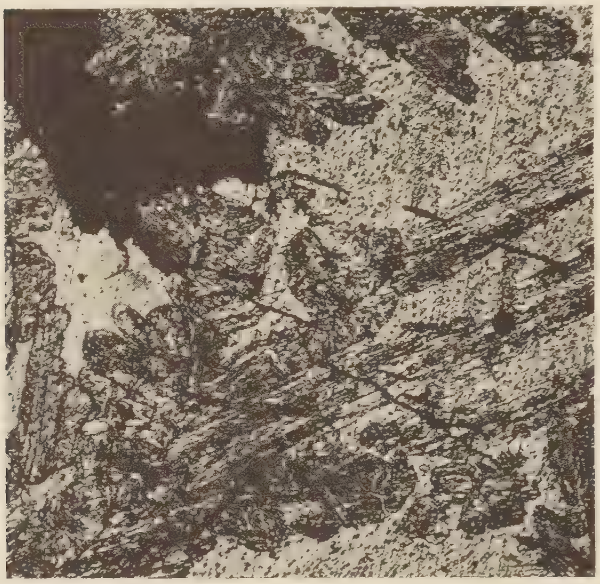

Fig. 11 Welded, Stainless, 18 Per Cent Chromium Steel Pitted by Water Jet
(Note fatigue and cleavage cracks. ×200.)

shown in Fig. 10 can be tested simultaneously mounted diametrically opposite to each other on the outer surface of the rim. There are two nozzles 180 deg apart directing water jets vertical to the plane of the disk. By this arrangement, each specimen is cutting one of the jets at the same time. A peripheral speed of 800 ft per sec was chosen providing 160,000 impacts during the six minutes of test duration. The jet diameters were 3/32 in. and the water velocity 60 ft per sec.

A series of runs carried out with specimens of identical material with the water temperature varying from 2 to 93 C indicated that the amount of pitting is in no way dependent upon the water temperature. This result when compared to that obtained with the cavitation tests leads to the conclusion that cavitation and water impact are fundamentally different. Aside from some minor inconsistencies explainable by the differences in the severity of the punishment, it was found that the losses obtained by the water-jet tests could be grouped similarly to those of the cavitation experiments. From this fact as well as from the photomicrographic analysis, the conclusion is drawn that the various factors governing the rate of pitting are nearly identical for both types of punishment. It is believed that for all practical purposes, the data in Tables 1 to 15 can be used as a guide for the selection of materials exposed to impact due to water jet or drops of water as present in impulse turbines and in the low-pressure stages of steam turbines, respectively.

General Conclusion

From a practical point of view the influence of the temperature indicated in Fig. 4 is important. Pitting apparently is more liable to occur in summer than in winter. In addition more serious consideration must be given to protective measures for equipment to be used in moderate-temperature regions or tropical climates where the water has a relatively high average temperature throughout the year.

The results obtained with air injection, presented in Fig. 5, are of interest because under the velocity conditions usually existing in hydraulic equipment, pitting can be reduced or prevented altogether in some locations, provided sufficient quantities of air can be introduced in such a way that the vulnerable areas are reached by the air. Model tests may be particularly helpful in obtaining proper guidance of the air. This is important because an adequate percentage of artifically introduced air over the entire water passage would be prohibitive from an economic point of view.

It is believed that the comparative data on the pitting resistance presented in this paper will be helpful in providing a more rational selection of materials for new installations, or for maintenance of structures or integral parts of hydraulic equipment subject to attack by cavitation. Although the number of materials investigated is necessarily limited, nevertheless the findings of the metallographic studies broadened the metallurgical aspects of failures due to cavitation to such an extent that, under modern manufacturing procedures and advanced scientific control of production, and with the aid of the results at hand, the pitting resistance of almost any metallic material can be predicted with sufficient accuracy. It must be borne in mind, however, that the resistance may not always be the only factor coming into play. Compromises may have to be made to satisfy all requirements including those dealing with the methods of manufacture and production, as well as the cost of the material and other economic considerations.

Acknowledgments

This research was made possible through the support received from J. A. Walls, president, Safe Harbor Water Power Corporation. The interest and cooperation shown by the research and metallurgical departments of steel and alloy manufacturers too numerous to mention individually are responsible in a large measure for the progress made. The author is particularly indebted to H. N. Boetcher, assistant to the superintendent of steam stations, Consolidated Gas Electric Light and Power Company, Baltimore, Md., and S. P. Watkins, metallurgist, Rustless Iron and Steel Corp., Baltimore, Md., for their contributions to the metallographic phase of this research.

Cavitation on Marine Propellers

By LYBRAND P. SMITH,[1] WASHINGTON, D. C.

The author defines terms used in connection with cavitation of marine propellers and hydraulic turbines. He points out that cavitation is a problem of growing importance where higher powers and speeds are required, and when cavitation occurs that thrust, torque, and efficiency are reduced and erosion of the hardest metals occurs. Theoretical and experimental research into the mechanics of cavitation and its effect on thrust, torque, and efficiency is reported. The author reports that the standard or usual equations for thrust and torque are merely special cases of a general thrust and torque theorem which he develops. He points out that cavitation on marine propellers is a phenomenon different from anything occurring on aerial propellers.

The author discusses the following items in detail: (*a*) In the general case, thrust and torque coefficients are functions of slip ratio, rotary speed, and pressure, and are not merely functions of slip ratio alone as is generally assumed. (*b*) For thrust and torque coefficients to be treated as functions of slip ratio only, the propellers must operate at low rotary speed or under high-pressure conditions. (*c*) Marine propellers operate under low-pressure conditions. (*d*) A simple equation indicates where burbling cavitation will begin on the back of any blade elements and what can be done to delay the appearance of such cavitation. (*e*) A vortex, in which the water particles move in approximately helical paths around the axis, is prerequisite to laminar cavitation. (*f*) A laminar cavity is not in contact with the propeller blade, but is separated therefrom by a wall of water. (*g*) Both kinds of cavitation can actually reduce thrust and torque with increasing rotary speed, and not merely reduce the thrust and torque below the values which would have been attained in the absence of cavitation, as is usually assumed. (*h*) After either type of cavitation completely covers the back of propeller blades, thrust and torque will increase again with increasing rotary speed, although at a lesser rate than in the absence of cavitation. (*i*) Both kinds of cavitation result in an increase of pressure on the cavitating side of the blade in excess of the pressure which would have existed in the absence of cavitation, and this accounts for the relatively small effect on thrust and torque when cavitation occurs on the face of the blade.

In conclusion, the author shows that previously reported explanations are inadequate to account for all the observed effects of cavitation on thrust and torque. He then develops his own theories to explain such effects, and shows that insight into actual physical phenomena has frequently been obscured by the otherwise useful custom of plotting results in the form of dimensionless, or quasi-dimensionless, coefficients against dimensionless products such as Reynolds' numbers or slip ratio.

1—INTRODUCTION TO THE EXPERIMENTS

A Field of Experiments in This Paper

THERE is a vast multitude of problems concerning marine propellers awaiting solution; but acting on the principle that one should "refrain from attempting too wide a field of inquiry," this paper will be confined to certain problems arising out of or in connection with the fact that cavitation occurs.

B Cavitation Definitions

Considerable confusion has arisen in the literature of cavitation by reason of the writers not having defined their terms. Usually they merely say "cavitation" or "cavity." More rarely they recognize two kinds of cavitation—"laminar" cavitation and "burbling" cavitation. Neither of the two preceding adjectives is particularly appropriate, but they have come into general use among writers who recognize that cavitation occurs in two quite distinct forms. To avoid confusion in comparing this paper with arguments of other writers the adjectives "laminar" and "burbling" will be retained, and defined along with other terms.

Definitions of the terms used in this paper are as follows:

(*a*) A cavity within a liquid is a single space void of liquid and bounded by a single surface, which may be wholly liquid or part liquid and part solid.

(*b*) A laminar cavity is a cavity stretched out in a long thin sheet or tube.

(*c*) A burbling cavity is a cavity in the form of a bubble, i.e., roughly spherical or in some cases hemispherical.

(*d*) A cavitation field is a region in a liquid bounded by a single envelope and containing a plurality of cavities—usually burbling cavities, but occasionally laminar cavities.

(*e*) In addition to defining cavitation by types it is sometimes referred to by location as tip, root, leading edge, trailing edge, face or back cavitation. None of these terms needs definition except "face" and "back." The face of a blade is the pressure side. The back of a blade is the suction side.

The foregoing definitions may be objected to as not being "operational" as Bridgman (1)[2] so rightly argues that scientific definitions should be. However, in the experiments subsequently described the operations will be indicated by which the

[1] Commander, United States Navy, Staff of Commander Battleships, Battle Force, U.S.S. *West Virginia*, flagship. Commander Smith was graduated from the United States Naval Academy in 1911, and later attended the University of Santo Domingo in 1919–1920, and the American University in 1933–1935; he received from the latter his D.Sc. degree in 1935. He served at sea from 1911 to 1919. From 1919 to 1921, during the military occupation of Santo Domingo, he held several cabinet posts in the Dominican Republic. He was commercial superintendent of Naval Communication Service from 1921 to 1923; senior assistant engineer, U.S.S. *Colorado*, 1923–1924, and chief engineer, 1924–1926. He was assigned to the repair division, Bureau of Engineering 1926–1928. Then he became Commanding Officer of the U.S.S. *Zeilin* and later the U.S.S. *Claxton*, 1928–1931. He was Officer-in-Charge of the U. S. Naval Boiler Laboratory from 1931 to 1933. He moved next to the boiler desk, design division, Bureau of Engineering and then in 1934 was assigned to the propeller desk of the same division with additional duty for research at the U. S. Experimental Model Basin. He was transferred to his present duty in 1936.

Contributed by the Hydraulic Division and presented at the Joint meeting of the Applied Mechanics and Hydraulics Divisions of The American Society of Mechanical Engineers, held at Cornell University, Ithaca, N. Y., June 25–26, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Note: Statements and opinions advanced in this paper are to be understood as individual expressions of the author, and not those of either the U. S. Navy Department or of the Society.

[2] Numbers in parentheses refer to the Bibliography at the end of the paper.

cavities can be created and be seen; and illustrations of actual cavities will be shown.

C Harmful Effects of Cavitation

Cavitation produces two seriously harmful results: (*a*) It causes rapid erosion, or corrosion, of propeller blades. (*b*) It reduces propeller thrust and torque; and usually efficiency.

Cavitation erosion will not be considered in this paper, although it is a live and important subject, with an extensive literature which a few works from one country (Germany) for one year will indicate (2, 3, 4, 5, 6). Nevertheless, cavitation erosion might be eliminated entirely, possibly by improvements in metallurgy, without in any way reducing cavitation or its effects on thrust and torque. On the other hand, the harmful effects on thrust cannot be reduced or eliminated without reducing or eliminating cavitation. Success with the erosion problem merely alleviates a symptom, success with the thrust problem cures the disease.

The author will deal mainly with marine propellers operating in or near the conditions under which cavitation may occur.

D Fundamental Difference Between Aerial- and Marine-Propeller Problems

Although the term "cavitation" is sometimes used loosely in connection with aerial propellers, it should be noted most emphatically that nothing in connection with aerial propellers corresponds to the cavitation of marine propellers.

In the latter case we have liquid water surrounding a space which is void of liquid, but which is filled with water vapor, usually mixed with air or other gases which have been dissolved in the water and are set free with the vapor as soon as the cavity is formed. We have, if you like, two different fluids, liquid water and a gaseous mixture.

In the former case we have regions of different pressure and density, but we do not have and cannot obtain a condition of separation into two fluids. We have only one fluid—air.

By the use of dimensionless products (for example, Reynolds' numbers) we can formulate many hydrodynamical equations or obtain empirical curves which are identical for a wide range of fluids such as water, oils, air, and various gases, flowing around solid bodies or through channels with rigid walls, so that experimental results with one fluid may safely be used for predicting the behavior of others. But in all such cases we are dealing with one continuous fluid at a time, while in the study of the cavitation of marine propellers the case is quite different. In this latter case we have to do with two separate fluids; and curves or equations that may be valid up to the beginning of cavitation cease to be applicable after the separation into liquid and gaseous phases, and cannot be used for extrapolation beyond this point.

E The Thrust and Torque Theorem

In short, if a marine propeller is operating in or near cavitation conditions it must be expected that equations used to describe its action will be more complex than those used to describe the action of an aerial propeller, or a marine propeller far outside of cavitating conditions. The nature of such equations is formulated as a theorem in this paper, and it will be shown that the standard equations used to describe propeller action are merely special cases of the more general equations.

It may be asked how such general equations will serve a useful purpose. As Sir Oliver Lodge said: "The answer is quite definite. The mathematical physicist probes down into the fundamental activities, so as to be able to formulate in his mind what is really going on, and to express the actions which can be observed in a definite and quantitative form called an equation, especially in that form called a differential equation, which expresses interactions among the smallest parts (7)."

This is to say that when a physicist has formulated such equations he has a definite picture in his own mind as to what is really going on, and this picture guides him to the experiments he should make to find the actual nature of the several factors in his equations. That has been the case in the present paper and the experiments made have yielded fruitful results. Among these results was emphasis on the previously known fact that pressure may play an important part in the performance of propellers, and this emphasis occurred in such a form as to raise the question: Do actual marine propellers normally operate within the range in which pressure is an important factor?

F The Pressure on Actual Propellers

The previous question led to a study of the pressure conditions on propellers for sea-going ships. The results of that study clearly show that, except in the case of deeply submerged submarines, marine propellers generally operate well within the range where pressure is an important factor in their performance. Therefore, pressure must be considered in the case of actual propellers.

G The Location of First Burbling and Laminar Cavitation

Cavitation has been shown to be an evil. To prevent an evil, one of the best methods is to learn where it begins and to eliminate it there. A deductive analysis will be made to find a theoretical answer to the problem: "Where does cavitation begin?" A verification of the resultant hypothesis will be sought and found in experimental observations.

H The Reason Cavitation Reduces Thrust and Torque

The general thrust and torque theorem formulated in this paper, the special cases of that theorem which are commonly accepted in standard texts, and the standard theories of propeller action do not indicate why cavitation reduces thrust and torque. Writers generally touch this subject very lightly, admitting or proving the occurrence of the phenomenon, but only hinting at a hypothesis for its explanation. From such writings tentative hypotheses will be formulated and discussed, and reasons shown for rejecting them. Then, in the present paper, a detailed discussion of the mechanics of cavitation will be given and a hypothesis will be formulated regarding how it produces the observed effects on thrust and torque. Experimental verification of the hypothesis will be given from experiments performed by other people for different purposes, and from experiments performed by the author for the particular purpose.

2—THRUST AND TORQUE THEOREM

A The Theorem

A fruitful method of studying the performance of any machine is to study the variations of its performance. Now it is an obvious platitude that while constants affect the absolute values in performance they do not and cannot cause variations in performance.

Thus, in the case of a given propeller such factors as its diameter, pitch, shape of blade, and roughness of surface, are constant. They affect the absolute values of that propeller's performance, but in no way can they be the cause of variations in its performance.

The two things we can vary in connection with the propeller itself are its revolutions per unit time N and its slip ratio S.[3]

[3] Slip ratio or slip is defined as $[1 - (v/pn)]$, where p = pitch of propeller, ft; n = propeller speed, rps; and v = speed of advance relative to undisturbed water, fps. When the pitch is variable, the mean face pitch at 0.7 radius is used as a matter of convention in defining the slip.

All other variables are properties of or refer to the surrounding medium itself.

Variations of the acceleration of gravity and of the compressibility of water are so slight (8) that for investigating marine propeller phenomena those factors may be considered constants which do not cause variations in performance.

Density, vapor pressure, viscosity, and surface tension of water all vary with temperature. Based on long experience at sea, the author will state that for practical purposes variations in the water temperature may be considered limited to the range between 4 and 35 C (39.2 and 95 F). To show the approximate magnitude of the variations produced in density, vapor pressure, viscosity, and surface tension by changes of temperature, the following data are extracted from the Smithsonian Physical Tables (9):

Temperature, C	4	35
Density, grams per ml	1.00	0.994
Vapor pressure, mm of Hg	6.10	42.23
Viscosity, centipoises (1 poise = 1 dyne-sec per sq cm)	1.57	0.72
Surface tension, dynes per cm	75	70.3

From the preceding data it is seen that density varies less than 1 per cent over the entire range of temperatures likely to be encountered. Since density is known to enter the performance equations as a linear function variations of density due to variations of temperature may be ignored. The difference in density between fresh and sea water, however, is over 2 per cent and cannot be ignored. In passing from fresh water to the average sea water the density changes from 1.0 to 1.024 at 39 F according to Saunders (10); but, as shown by Taylor (12), if we test a propeller in fresh water we can predict the results in sea water by multiplying the thrust and torque obtained in fresh water by 1.024.

Variations in surface tension may conceivably cause variations in formation of cavities. Variations in viscosity certainly must produce some variation in the frictional drag on propellers. But the net effect of these variables apparently may be ignored with safety, since it is so small that it has not been detected in the performance of the more than 1500 model propellers which have been tested by the personnel of the U. S. Experimental Model Basin to date (1936).

The vapor pressure of water e varies too much and in too great an amount to be ignored, particularly when cavitation on a small propeller is likely. At 39.2 F the vapor pressure is equivalent to the pressure of 0.27 ft of water; and at 95 F increases to 1.89 ft of water.

The absolute pressure P at the propeller axis is obviously the sum of the atmospheric pressure on the surface of the water and the pressure due to the submergence of the propeller. This absolute pressure P can be expressed, of course, in the same terms as e; for example, in ft of water.

It is logical then to combine P and e, if possible, in order to reduce the number of variables. Note that if P is varied, either by a change in atmospheric pressure or in depth of submergence, the result is merely to change the static pressure by the same amount at all points in the water and is not to change the pressure gradients. But, if at any time at any place in the liquid $P - e = 0$ the liquid will boil at that place except under highly specialized conditions of cohesion experiments such as reported by Newton (16), Dixon and Joly (17, 18) and Livingston and Lubin (19, 20). This may be expected to disturb the pressure gradients and consequently the forces acting on the propeller.

Hence, let H be a new variable compounded of P and e such that $H = P - e$ = pressure in excess of vapor pressure at the propeller axis; and let it be expressed in terms of feet of pure water.

Clearly, then we have so limited the number of significant variables that we can write

$$T = f(S, N, H) \qquad [1]$$

$$Q = \phi(S, N, H) \qquad [2]$$

where T is the thrust in lb; Q is the torque in lb. at 1 ft radius; as previously defined, S is the slip ratio;[3] N is rpm; and H is the pressure in excess of vapor pressure at the axis of the propeller.

One of the most fruitful methods to study Equations [1] and [2] would be by the method of dimensional analysis. Taylor (12) has followed this method though he has ignored H in all his equations, and merely reports the results of a few experiments when H is reduced, without endeavoring to determine how that quantity should enter the equations. Schaffran (21) and Baker (22) have followed a procedure analogous to Taylor's (12). An article by Buckingham (25), published after the preparation of this paper, is believed to be the most thorough study to date of dimensional analysis with propellers, and is probably the only one which fully applies this mathematical principle to cavitation.

It is believed that the method of dimensional analysis is the most all around useful method for this purpose. However, it has been very thoroughly exploited—in spite of previous writers other than Buckingham not having included H in their dimensional equations—and the author believes that new experiments will be suggested, a new viewpoint will be gained, and possibly a further insight into the mechanism of cavitation will result if Equations [1] and [2] are studied by another method.

The method proposed is to convert Equations [1] and [2] into differential equations. Doing this we obtain

$$dT = \frac{\partial T}{\partial S}dS + \frac{\partial T}{\partial N}dN + \frac{\partial T}{\partial H}dH \qquad [3]$$

$$dQ = \frac{\partial Q}{\partial S}dS + \frac{\partial Q}{\partial N}dN + \frac{\partial Q}{\partial H}dH \qquad [4]$$

Equations [3] and [4] constitute the thrust and torque Theorem.[4]

This theorem almost automatically directs us to perform systematic experiments or operations with everything constant except S; with everything constant except N; and with everything constant except H. We would thus obtain what might be called: (*a*) T-S and Q-S curves; (*b*) T-N and Q-N curves; (*c*) T-H and Q-H curves.

In view of the foregoing discussion this may seem a perfectly obvious procedure. But apparently it is not. In the examination of a very wide range of literature the author has discovered only one set of experiments with a variable H and a constant S and N, but the exact variation of H was not given as only the variation of P was mentioned, and the water temperature was not recorded. All "characterization curves" are forms of the T-S and Q-S curves; but since they are expressed in the form of thrust and torque coefficients they are supposed to be good for any values of N and there is rarely any indication at what N they were obtained. By questioning people who obtained such curves the author has found that it is not at all unusual to vary N at convenience during any one test. He has never in any case found an experiment with S and H held constant while N was varied. And especially, he has never found a case where the

[4] According to Funk and Wagnall's New Standard Dictionary a theorem is, among other things: "A proposition not self-evident that is demonstrably true or acknowledged as such; . . . a rule or law formulated in symbols, or the directory of an operation."

complete set of operations directed by the thrust and torque theorem was carried out for any one propeller.

Since Equations [3] and [4] are similar in form, only Equation [3] for thrust will be discussed in detail; although experiments directed by the theorem will be made to demonstrate that both Equations are true.

B Usual Equations Are Special Cases

The standard or usual equations for the thrust and torque of a given propeller are merely special cases of the foregoing more general theorem.

The standard equation for thrust as given by Taylor (13) is

$$T = C_T n^2 p^2 d^2 \qquad [5]$$

where C_T = thrust coefficient; n = propeller speed, rps; p = pitch of the propeller; d = propeller diameter; and there is a similar equation for torque involving p^3 in place of p^2. Shaffran (21) uses equations of the same form as Taylor's. These standard equations are entirely analogous to standard equations for lift of airfoils (26), such as

$$L = {}^1/_2 C_L \rho V^2 A$$

where L = lift; V = velocity; A = area of foil; ρ = density of medium; and C_L = experimentally determined lift coefficient.

In Equation [5], d^2 corresponds to A in the lift equation; N^2p^2 at a given slip corresponds to V^2 at a given angle of attack; and ρ does not need to appear in Equation [5], because it is sensibly constant for water.

Equation [5] is, in reality, a definition of C_T, because by writing it in the form

$$C_T = \frac{T}{n^2p^2d^2} \qquad [6]$$

we can always get a definite value of C_T, for a propeller of known pitch and diameter, by substituting simultaneously observed values of T and N. Thousands of such determinations of C_T for hundreds of model propellers have been made in open-water tests in which the propellers have not been driven up to the cavitation point. When the values of C_T, obtained from such tests of any one model propeller, are plotted against the slip ratio S, the points lie so closely along a single curve that it is reasonable to assume that deviations from the curve are due to accidental errors of measurement, and thus to assume that, in the absence of cavitation, C_T depends only on S, so that

$$C_T = f(S) \qquad [7]$$

Equation [5] may then be rewritten as

$$T = p^2d^2n^2f(S) \qquad [8]$$

or letting $p^2d^2 = k$ = a constant for the given propeller

$$T = kn^2f(S) \qquad [9]$$

This is of the general form

$$T = f(N, S) \qquad [10]$$

N being by definition the number of revolutions in *any* unit of time

whence

$$dT = \frac{\partial T}{\partial N}\,dN + \frac{\partial T}{\partial S}\,dS \qquad [11]$$

Therefore, it may be said that the standard Equation [5] as usually understood on the tacit assumption that there is no cavitation, is a special case of the more general equation, that is, Equation [1].

When we drop this restriction regarding cavitation, Equations [7] to [10], inclusive, are no longer adequate. Taylor cites a case (14) illustrative of results obtained in the variable-pressure water tunnel at various constant values of total absolute pressure, which of course would correspond to various constant values of the total head H above vapor pressure. (See the discussion under section 2A of this paper.) Under such conditions the curves of C_T versus S do not coincide over their whole range; on the contrary, at high values of S the value of C_T for a given value of S depends on H. Hence, although Taylor does not state it in just this way, we know that, in general C_T depends on H as well as on S.

From this we might incautiously infer that C_T depended only on S and H, and write in place of Equation [7]

$$C_T = F(S, H) \qquad [12]$$

which would put Equation [5] into the form

$$T = kn^2 F(S, H) \qquad [13]$$

The inference would, however, be incorrect; for as will be demonstrated clearly in the following sections reporting the author's experiments, C_T is not completely determined by S and H but depends also on N, so that in place of Equation [12] we must write

$$C_T = F_1(S, N, H) \qquad [14]$$

and in place of Equation [13]

$$T = kn^2 F_1(S, N, H) \qquad [15]$$

But this is merely a statement that

$$T = f(S, N, H) \qquad [16]$$

which is the original Equation [1].

Equation [15] makes it evident that, in general, the variations of T with N alone follow a more complicated law than $T \propto N^2$, as indicated by Equation [9] although Equation [9] is adequate for practical purposes to represent the results of open-water tests which stop short of cavitation. The experiments to be described show that the simpler relation is a special case of the more general theorem, and that in order to get the simpler relation it is necessary to avoid cavitation by making the total head above vapor pressure H large; or the rotary speed N small.

A similar chain of reasoning and the same experiments prove that in general the torque coefficient C_Q, is

$$C_Q = F_2(S, N, H) \qquad [17]$$

and that the torque Q is

$$Q = kn^2 F_2(S, N, H) \qquad [18]$$

C Nature of the Experiments[5]

In Equation [3] the partial differential coefficient of T with respect to S, i.e., $\partial T/\partial S$, is the rate of change of thrust with respect to slip alone. Hence, if N and H are held constant at any values and S is varied we obtain a T-S curve. The slope of this curve at any point is obviously $\partial T/\partial S$. It would be possible, of course, to produce families of T-S curves for various constant values of N and H. A similar procedure with respect to Q yields the Q-S curves.

[5] The experiments reported in this paper were all conducted at the U. S. Experimental Model Basin, Washington, D. C., and especially in the variable-pressure water tunnel. For a description of the apparatus see articles by Saunders (10, 32). Since Saunders last-mentioned article (32) was written, the principal improvements in the water tunnel have been (*a*) better control and measurement of water velocities; (*b*) heat insulation of the tunnel; (*c*) the installation of an Edgerton stroboscope; and (*d*) photographic apparatus.

The same remarks apply to the partial differential coefficients $\partial T/\partial N$, $\partial Q/\partial N$, $\partial T/\partial H$, and $\partial Q/\partial H$. In gathering the data which could yield numerical values for these coefficients we should obtain families of *T-N*, *Q-N*, *T-H*, and *Q-H* curves.

In order, then, to demonstrate that the thrust and torque theorem is true, and sheds some light on marine-propeller phenomena not yielded by the standardized equations, experiments of the following nature are necessary: (*a*) Determine the *T-S* and other curves previously mentioned. (*b*) Study them to see if they indicate any phenomena not predicted by the standard equations; and if so (*c*) try to account for such phenomena by observing cavitation characteristics, if any.

It would be desirable, of course, to run all of these curves over a very wide range to obtain a large family of such curves, and to do this for a large number of propellers.

The limitations of the apparatus prevent as wide a range of observations as would be desirable. It is obvious that there would be upper limits to the water speeds, revolutions, thrust torque, and pressures which could be placed on any particular apparatus. It is not so obvious, but equally true that for practical purposes there are lower limits, particularly in the case of water speeds. At very low water speeds it is practically impossible to control conditons in the tunnel, because minute changes will cause the propeller under test to control the water speed at times, and at other times the tunnel's impeller will control it. The result is a series of irregular surges, which render observations useless. It may be stated now that in every case the experiments were run over as wide a range as physically permissible with the available apparatus.

Time and funds available prevented obtaining as large a family of curves for as many propellers as desirable. There is only one variable-pressure water tunnel and it is in almost constant use on urgent government work. The best procedure seemed to experiment as thoroughly as possible with a few propellers, and to observe all the routine governmental tests possible. Should the latter, which cover a wide variety of propellers under a wide variety of conditions, ever yield an observation at variance with the hypotheses resulting from the experimenter's research, that would be definite evidence that something was wrong with his hypotheses. The absence of such negative instances would not prove his hypotheses right. The lack of negative instances would merely increase the probability that the hypotheses were right. For example, there is no *a priori* reason to assert that "The uniformity of nature" is a true hypothesis. But after diligent search over a wide field a negative instance has never been found. This increases the probability that the hypothesis is right.

D Selection of Propellers for Experiment

Since, as stated previously, the actual experiments had to be limited to a few propellers, and since it is desirable to study cavitation, it seemed wise to find two propellers differing as widely as possible in their cavitation characteristics.

There are two radically different kinds of cavitation—"burbling" and "laminar" as stated previously. The characteristics of about 1200 model propellers were studied and two groups selected, one of which was likely to cavitate mainly in the laminar manner and the other in the burbling manner. These limited groups were then run through cavitation to check the records, and propeller model No. 1283-*A* was selected as the most typical of laminar cavitation,[6] and propeller model No. 414 was selected

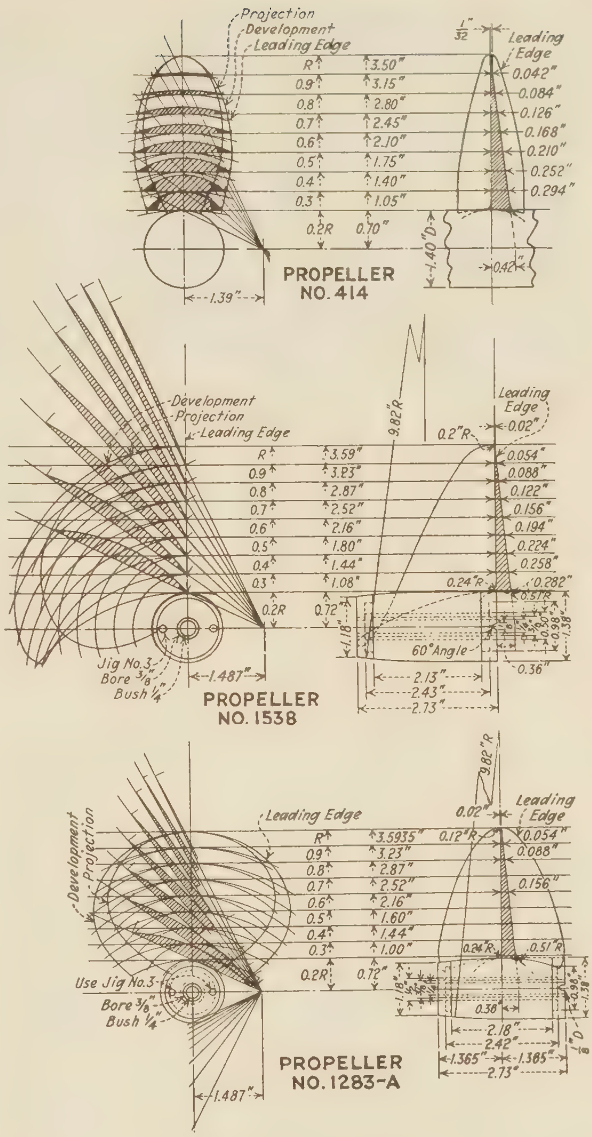

Fig. 1 Details of Propellers Selected for Cavitation Tests

Characteristics of the Propellers

Propeller no.	414	1583 and 1283-*A*
Diameter, in.	7.000	7.187
Pitch, in.	8.750	9.340
Pitch ratio	1.250	1.300
Mean width ratio	0.200	0.500
Number of blades	3	3
Total projected area	9.432	25.580
Ratio of projected area to developed area	0.245	0.630
Blade thickness fraction	0.060	0.050
Direction of rotation	right	right
Length of sections from T.E. to maximum ordinate at the following percentages of the radius:

as the most typical of burbling cavitation. As an additional check one freak-type propeller (No. 1538) was manufactured for comparison with No. 1283-*A*, all dimensions being held as nearly the same as was possible for the pattern maker to work, the es-

[6] Propeller model No. 1283-*A* was originally No. 1283. A small amount of metal was scraped from the back near the leading edge of the root sections, and the designation *A* added to call attention to the fact that a slight change had been made. All experiments reported in this paper were made after this minor alteration.

sential difference being to shift the tangential sections to make the leading edge a radial straight line.

The complete details of these propellers are shown in Fig. 1. The open-water characterization curves of propellers 1283-*A* and 414 are shown in Fig. 2. Fortunately some of the low-pressure runs were made with propeller 1538 before any attempt was made

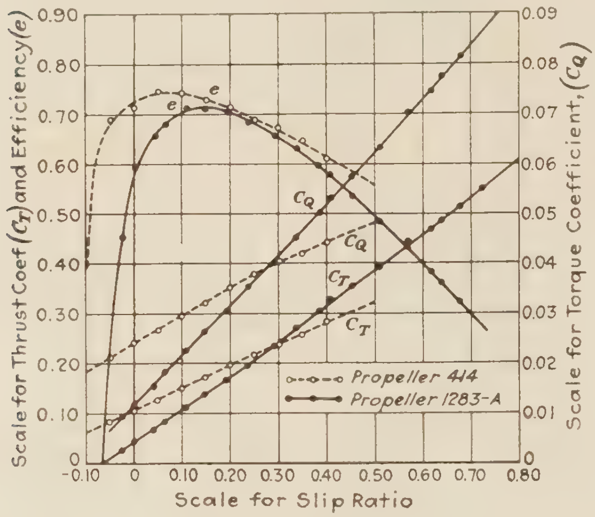

FIG. 2 OPEN-WATER CHARACTERISTIC CURVES FOR PROPELLERS 414 AND 1283-*A*

($C_Q = Q/n^2p^3d^2$; $C_T = T/n^2p^2d^2$; $e = Tv/2\pi Qn$; and Slip $S = (pn - v)/pn$ where Q = torque, ft-lb; T = thrust, lb; n = rps; v = speed of advance, fps; p = pitch, ft; and d = diameter, ft.)

to obtain its open-water characteristics; because, owing to its freak construction, it was inherently weak. The blades bent while running experiments to obtain the *T-N* and *Q-N* curves; they were repaired, and then the propeller was run to destruction as the higher pressures were reached while obtaining the *T-H* and *Q-H* curves.

[Editor's note: Sections *E*, *F*, and *G* of part 2 of the paper which follow have been condensed. However, the author's original manuscript giving details of all his observations is on file in the archives of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, together with excerpts from a letter in which he discusses probable error.]

E EXPERIMENTAL DETERMINATION OF THE *T-S* AND *Q-S* CURVES

The set of tests which should be first considered, the results of which are presented graphically in Fig. 3, were made with constant pressure *H* in excess of vapor pressure and with constant revolutions *N* for each series, the slip ratio *S* being varied in order to show thrust *T* and torque *Q* as functions of *S*.

For propeller 1283-*A*, three series of runs were made at 800, 1200, and 1600 rpm, respectively. The water temperature was 76 F for all runs corresponding to a vapor pressure of 1.02 ft of water, and *H* was maintained at 2.00 ft. For propeller 414, two series were made at 855 and 1282 rpm, respectively, and although the temperature of the water varied slightly, *H* was as before maintained at a constant value of 2.00 ft of water. Unfortunately no comparable tests could be made for propeller 1538 for the reason that this propeller failed mechanically during tests that although conducted earlier are more logically discussed in the following section of this paper.

Fig. 3 shows the characteristics of the two propellers that could be tested in this way, and brings out very forcibly the essential fact that in the general case thrust and torque are not simple functions of *S* alone; and that *T* and *Q* vary with *N* by some relation that is more complicated than the second power. In order to make a little more clear the fallacy of the simple equations used at the outset of this paper, the observed values have been reduced to thrust and torque coefficients and plotted for comparison with the corresponding open-water curves taken from Fig. 2. It is to be noted that in the case of propeller 1283-*A* most of the points fall sufficiently close to these repeated curves to indicate that the fundamental equations do hold up to a point where there is a definite breaking away, and that from there on the relation is complicated. In the case of propeller 414, the observations for the lower speed agree reasonably with the previously determined open-water curves, but for the higher speed something has already taken place even at the lowest slip ratio for which measurements were taken, which causes both the torque and the thrust to be not in accordance with the open-

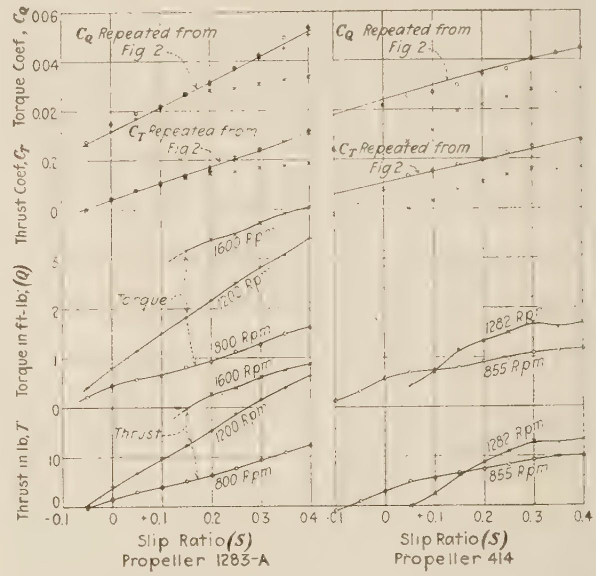

FIG. 3 SLIP CHARACTERISTICS OF PROPELLERS 414 AND 1283-*A*

(Pressure *H* at hub, in excess of vapor pressure = 2 ft of water. Note that at 1282 rpm propeller 414 cavitates even at low slip ratios.)

water tests. In fact, the effect is so marked that there is an actual crossing of the observed curves, and it should be noted particularly that until the slip is near 20 per cent this propeller gives less thrust at 1282 rpm than it does at 855 rpm.

It is obvious that since thrust and torque are shown so conclusively to vary not by any simple function of N^2, it is necessary when presenting curves C_Q and C_T as functions of *S*, that *N* at which the values were obtained should be indicated.

The following step is to investigate further the influence of *N*.

F EXPERIMENTAL DETERMINATION OF THE *T-N* AND *Q-N* CURVES

In the preceding section 2E it was demonstrated that *N* did have an influence on the characteristic *T-S* and *Q-S* curves. The task is now to investigate further by holding other elements constant and varying *N* progressively, at the same time observing visually the appearance of the back side of the blade and repeating with different values of pressure *H* and slip ratio *S*. Furthermore, all three model propellers were used to demonstrate the characteristic differences in type of cavitation arising from the peculiarities of design.

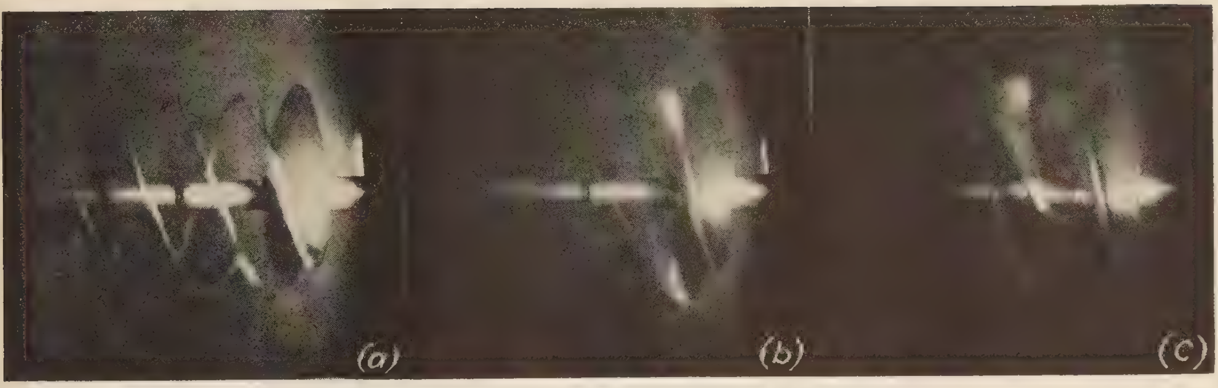

Fig. 5 Propeller 1283-A as Seen by Light of the Edgerton Stroboscope Operating at Three Different Speeds With 35 Per Cent Slip in Water Pressure of 1.37 Ft in Excess of the Vapor Pressure. The Water Flow Is From Right to Left

((a) At 924 rpm the dark patch which appears to rest on the tip of the back (suction side) of the blade is laminar cavitation, so called because from this point of view it appears as a thin, smooth, sheet-like cavity lying on the blade. Note that this cavity trails astern like a twisted ribbon. (b) With the speed increased to 1155 rpm the laminar cavity has covered more of the back. To the eye, when accommodated to the light, the vortices trailing astern did not present such a frothy appearance as in the photograph (which consists of pictures taken by about ten flashes superimposed on each other), but did appear as a larger form of the tip vortices shown in (a). (c) Speed still further increased to 1616 rpm. The laminar cavity now extends nearly to the root of the blade and covers practically the entire back.)

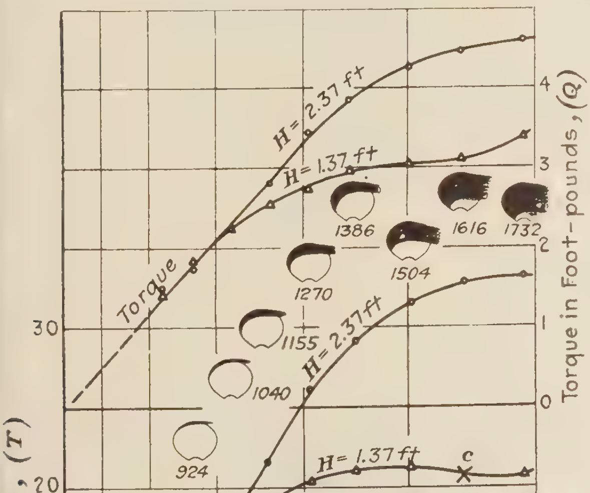

Fig. 4 Torque-Speed and Thrust-Speed Curves for Propeller 1283-A at Two Pressures

(Letters a, b, and c refer to Fig. 5. H = pressure at hub, in excess of vapor pressure, ft of fresh water. Slip ratio = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation; the proportion of blade area covered by cavitation as indicated is probably correct within ± 5 per cent. Cavitation indicated is all on the back (suction) side of the blade.)

Fig. 4 shows T and Q plotted against the square of the speed for the first two runs on propeller 1283-A, the slip in both cases being 0.35, but H in the first run was 2.37 ft of water in excess of the vapor pressure and 1.37 ft in the second. There is evidence that both the torque and the thrust vary in direct proportion to the square of the speed only to the point where cavitation becomes evident. For both pressures this ratio is the same, but at the lower pressure the breaking away from the common straight line is at a much lower value than for the higher pressure. It will be seen that the break away is intimately connected with the change of appearance of the back side of the blade.

Fig. 5 shows illustrations a, b, and c taken at the stages in this second series marked by the points a, b, and c on Fig. 4.

In order to demonstrate more clearly than was possible with the conditions selected for the first two runs, two conditions were changed in the third, both being conducive to greater cavitation. In the first place the slip was increased from 0.35 to 0.45, and also the pressure was still further lowered to 1.04 ft of water. As will be seen later, this third run affords a much better comparison with the other models and lays a foundation for the subsequent argument.

The results of this series are shown in Fig. 6. The straight diagonal lines from which the test curves would have broken away if they had been carried downward to the range of very low speeds were derived from the open-water tests and the dashed portion of the curve seems amply justified in the light of the previous results. The form of both the T-N and Q-N curves is very important and should be carefully noted on account of the subsequent importance in the development of the theory proposed. Terms $\partial T/\partial N$ and $\partial Q/\partial N$ will be referred to frequently, and it should be remembered that $\partial T/\partial N$ and $\partial Q/\partial N$ are simply the slopes of these two curves, which will be seen to vary from positive to negative values and then return to positive again. The same characteristic will be seen for all of the models.

In the upper part of Fig. 6 is represented the coefficients C_T and C_Q, respectively. The solid curves are plotted through the observed points, whereas the dashed portion is derived from the corresponding portion of the lower curves. If the breaking away from a diagonal at very low speeds is to be accepted, it then follows that the curves representing the coefficients likewise break away from a horizontal straight line. It is also important to note that both coefficients which start as horizontal straight lines pass through a transitional stage and then as cavitation becomes more fully developed approach horizontal lines again.

Fig. 7 shows the corresponding results, both graphical and visual for propeller 414 with S = 0.35 and H = 1.92. The same characteristic shape of the curve will be observed,

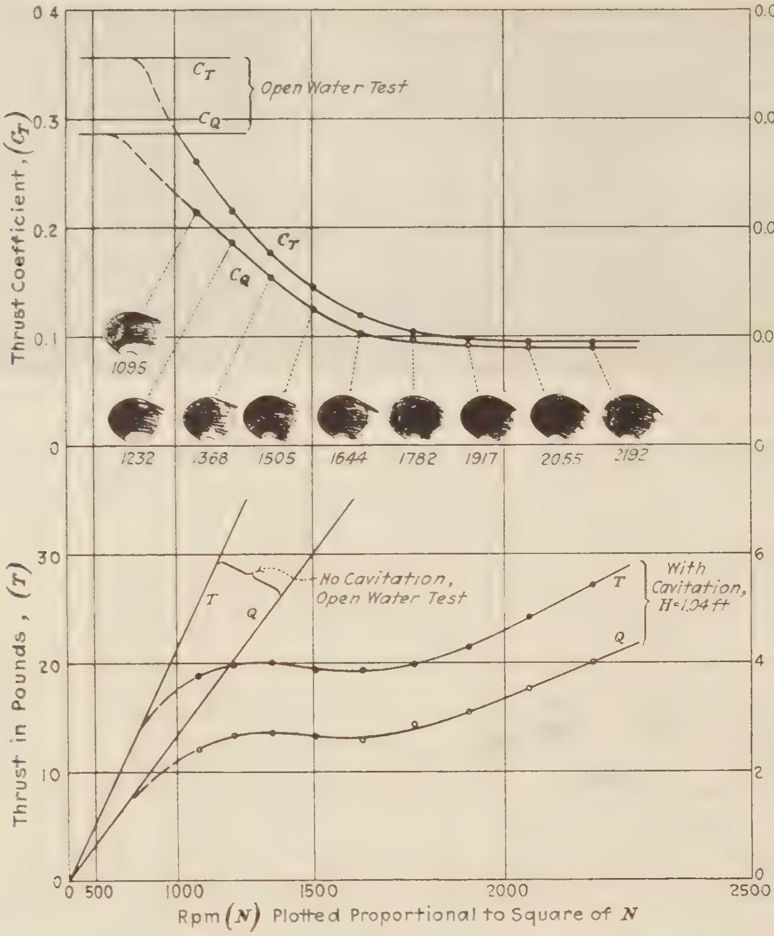

FIG. 6 CURVES OF T, Q, C_T AND C_Q VERSUS N FOR PROPELLER 1283-A

(Pressure H at hub, in excess of vapor pressure = 1.04 ft of water; for open-water test H is large. Slip ratio = 0.45. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation as indicated is all on the back of the blade, i.e., the suction side.)

although the appearance of the cavitation is distinctly different.

The view shown in Fig. 8 was taken under rather unfavorable conditions, but for what it is worth shows the early stages of burbling cavitation. The light of the stroboscope is dim, and it is first necessary for the eye to become accustomed to it, and then the individual bubbles will be seen distinctly. However, in order to photograph these it requires a number of flashes and the resultant picture is vague. The apparent roughness is made up of rapidly moving bubbles. A photograph probably made by the light of a single electric spark presented by Cook (33) is reproduced by courtesy of the Institution of Naval Architects as Fig. 9. Shortly after the completion of these experiments better photographic apparatus was available, and excellent pictures could be obtained with the Edgerton stroboscope. Fig. 10 is an example showing individual bubbles and the beginning of tip vortices.

Fig. 11 shows the corresponding tests for propeller 1538 with slip S of 0.35 and H of 1.37 ft. Here the open-water test was not available to derive the straight portion of the curves, but the observed data show very clearly the general breaking away and, in particular, the distinct S shape of the curves of C_T and C_Q. It is also important to note on the sketches in Fig. 11, showing the visual appearance of the blades, the combination of burbling cavitation and the peculiar tip vortex which does not advance down the leading edge as in the case of propeller 1283-A. Unfortunately at the higher speeds the inherent structural weakness of this freak design led to mechanical failure of the blade following a bending of the tips. This caused the last two points to be displaced as indicated, and also prevented the open-water tests from being made.

Summing up the observations common to all of the models:

(a) By comparing the curves with the cavitation characteristics, it is evident that there is a correlation between the amount of cavitation and the departure of these low-pressure T-N and Q-N curves from the high-pressure T-N and Q-N curves taken from open-water characterization. This departure increases progressively as the amount of cavitation increases; until cavitation covers substantially the whole back of the blade, and from then on the departure maintains an approximately constant ratio to the high pressure T-N and Q-N curves.

(b) Since $\partial T/\partial N$ and $\partial Q/\partial N$ are the slopes of the T-N and Q-N curves, it is apparent that both $\partial T/\partial N$ and $\partial Q/\partial N$ are positive up to maximum values, pass through zero and become negative, reach minimum values, pass through zero again and become positive.

(c) It is clearly apparent that T and Q vary with N by some relation more complicated than varying as N^2; because, if T and Q varied directly as N^2, the T-N and Q-N curves would plot as straight lines when the abscissas are proportional to N^2, while the

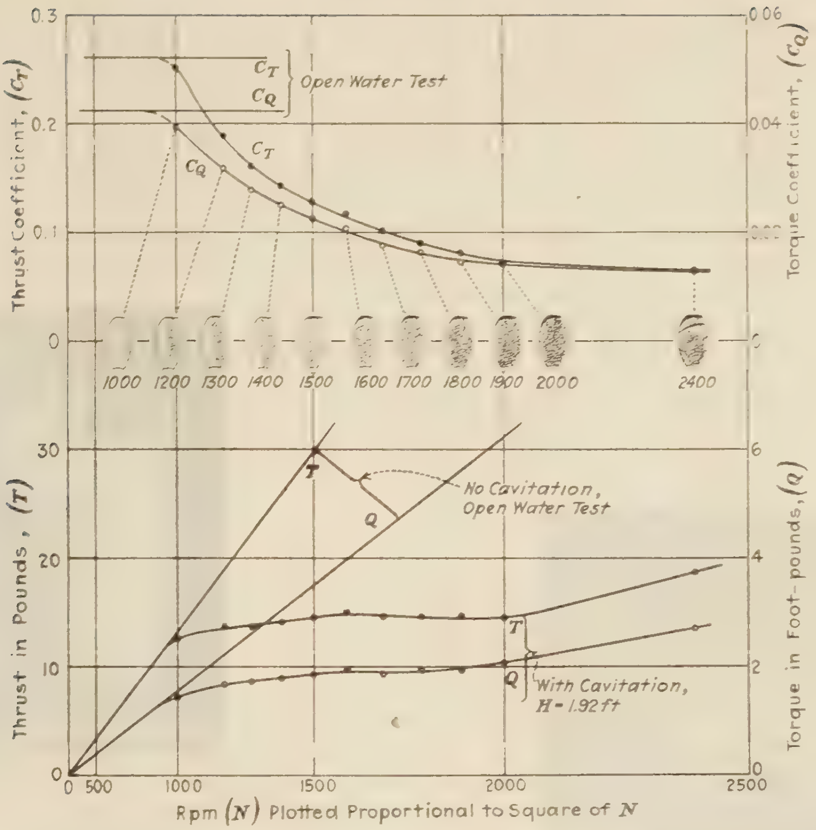

Fig. 7 Curves of T, Q, C_T and C_Q Versus N for Propeller 414

(Pressure H at hub, in excess of vapor pressure = 1.92 ft of water; for open-water test H is large. Slip ratio = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation as indicated is all on the back side of the blade, i.e., the suction side.)

actual curves under cavitating conditions are far from straight.

(*d*) An examination of the C_T and C_Q curves shows definitely and conclusively that those coefficients are not functions of S alone but are also functions of N. It is to be noted that C_T and C_Q seem to be approaching some constant value as N increases; and that probably, at very high values of N, and with cavitation covering the entire back of the blade, C_T and C_Q become constant for a given S and H without regard to further increases of N.

These are only the principal points as a more thorough discussion is reserved for part 5 of this paper.

G Experimental Determination of the T-H and Q-H Curves

In order to complete the investigation of the effect of the several variables upon the thrust and the torque, it remains to select a definite speed and slip ratio, and vary the pressure progressively over wide limits, at the same time noting the visual appearance of the back side of the blade. Figs. 12, 13 and 14 show the results for propellers 1283-*A*, 414, and 1538, respectively. Inasmuch as T and C_T are proportional to each other, and the same is true of Q and C_Q, when N is constant, the curves for T and Q have been omitted. The absolute values of thrust and torque do not contribute anything to clearness and the values of the coefficients are more readily comparable with the coefficients in previous curves.

A number of interesting deductions might be made from these figures, but it is desired to emphasize only two points at this time: (*a*) Examination of the curves shows clearly that, in the general case, thrust and torque coefficients are functions of H; and that $\partial T/\partial H$ and $\partial Q/\partial H$ do not become zero until relatively high pressures are reached. (*b*) Taylor (12, p. 91) has shown that, if it is desired to have comparable conditions on similar propellers of different sizes, the pressures on the two sizes must bear the relationship

$$P_{1/D} = p_{1/d}$$

where P_1 and p_1 = the pressures on the large and small propellers, respectively, and D and d = the diameters of the large and small propellers. Consequently if P_1 and p_1 are expressed in feet of fresh water, division by the corresponding diameter in feet gives pressures in propeller diameters of fresh water. If, instead of recording the pressure on a propeller in pounds per square inch or in feet of water, we record it in propeller diameters of fresh water we have a ready means of making a quick estimate of how the pressures on full-size propellers on sea-going ships compare with the pressures on models. For this reason an auxiliary scale was placed on the *T-H* and *Q-H* curves showing the pressures in excess of vapor pressure in propeller diameters of fresh water. This idea of using propeller diameters of fresh water as a unit of measurement greatly facilitates studying the pressure on full-size sea-going propellers, and such a study is presented in part 3.

3—PRESSURE ON SEA-GOING PROPELLERS

A Introduction

The *T-H* and *Q-H* curves of Figs. 12, 13, and 14 make it obvious that when there are high pressures on propellers a change of pressure has very little, if any, effect but that at low pressures a

slight change of pressure has a very great effect. There is no sharp dividing line between high pressures and low pressures but from a study of the curves it is reasonable to define "high pressures" as pressures at the hub above 20 propeller diameters of fresh water; and "low pressures" as pressures below 10 propeller diameters of fresh water leaving the region between as indeterminate.

The question then arises: Do actual sea-going propellers operate in the high-pressure, in the low-pressure, or in the indeterminate-pressure zone?

Since the pressure zones are so broad in terms of propeller diameters, since actual propellers always have at least full atmospheric pressure on them, and since sea-going propellers are usually large, we can ignore vapor pressure in the case of actual propellers. For example, if the vapor pressure equals 1 ft of fresh water and the propeller is 10 ft in diameter, then the vapor pressure equals only 0.1 propeller diameter of fresh water, which is negligible when we are considering pressure zones as broad as previously discussed.

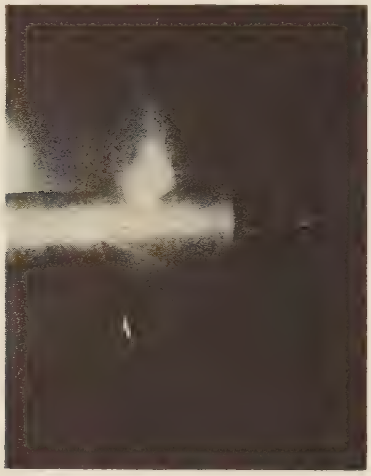

Fig. 8 Propeller 414 in Early Stages of Burbling Cavitation While Taking T-N and Q-N Data

(The roughness which appears on the back (suction) side of the blade is composed of individual bubbles which can be seen distinctly when the observer's eyes become accommodated to the light, but which cannot be photographed distinctly with the author's equipment. See Fig. 9.)

Hence, in order to answer our question a number of cases were chosen at random from merchant and naval surface ships and submarines. The following procedure was followed: (*a*) Hub submergence was taken from the plans for designed mean draft in sea water for surface vessels and draft aft for submarines. (*b*) This was converted to an equivalent pressure in feet of fresh water. (*c*) To this was added, as equivalent to the pressure of a standard atmosphere, 33.93 ft of fresh water. (*d*) This sum was divided by the propeller diameter in feet to obtain the pressure in propeller diameters of fresh water at the hub. (*e*) The vapor pressure was ignored for reasons previously stated.

Data for 66 surface ships and six submarines were examined by the foregoing procedure. The 66 surface ships included battleships, heavy cruisers, light cruisers, aircraft carriers, destroyers, a destroyer tender, an ammunition ship, a store ship, a transport, a repair ship, a submarine tender, an aircraft tender, a trawler, bay tugs, an ocean tug, a rescue tug, freighters, passenger ships of all classes, a training ship, and a passenger ferry.

The following is a summary of the results: The arithmetic mean of absolute pressures at the hub in terms of propeller diameters of fresh water was 3.7 and 6.0 for surface ships and submarines, respectively. The standard deviation from the mean was 0.69 and 0.61 for surface ships and submarines, respectively.

B Sea-Going Propellers Operate Under Low-Pressure Conditions

The data in the preceding section 3A make the conclusion inescapable that the propellers of sea-going vessels, including submarines running on the surface, operate under low-pressure conditions. Even the submarines would have to submerge about 100 ft before their propellers could be considered as working under high-pressure conditions.

Fig. 9 A Typical Example of Burbling Cavitation
(Courtesy of the Institution of Naval Architects, London.)

Fig. 10 Typical Burbling Cavitation and the Beginning of Cavities in Tip Vortices

(Taken with improved photographic equipment installed at the U. S. Experimental Model Basin after the completion of the author's experiments.)

The previous part of this paper (see particularly 2B) shows that two conditions, a high-pressure (large H) or a low rotary speed (small N), are required in order that the variations of propeller thrust (T) with N alone should follow the simple law that $T \propto N^2$; and that the thrust coefficient (C_T) should be a function of slip only; and likewise for torque and its coefficient.

This part of the paper, that is, part 3 demonstrates that, except in the case of deeply submerged submarines, one of these two conditions (large H) is not met in sea-going vessels. Consequently,

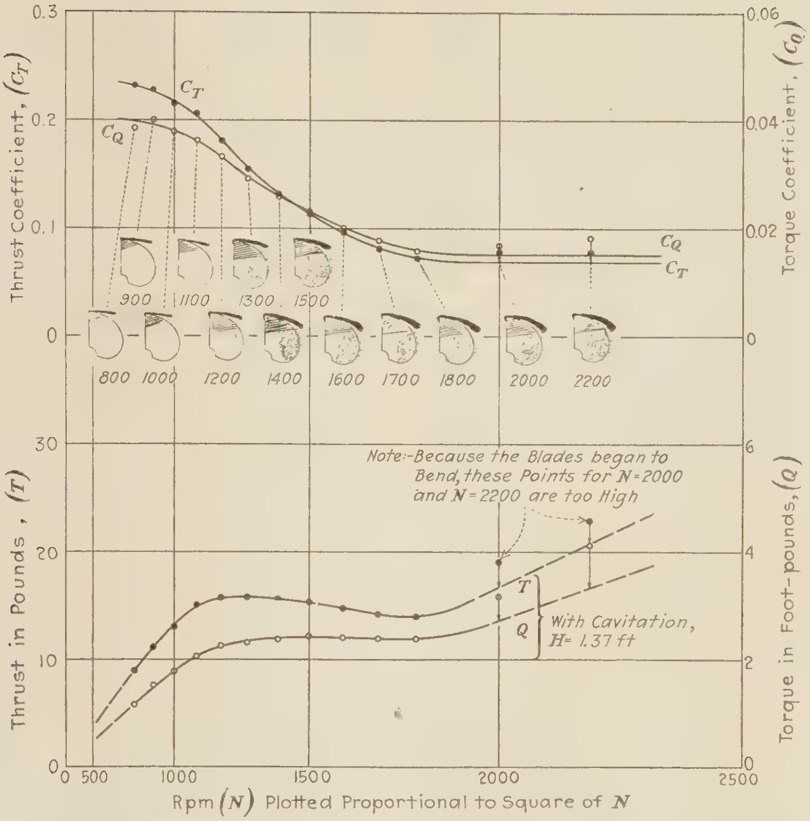

FIG. 11 CURVES OF T, Q, C_T, AND C_Q FOR PROPELLER 1538

(Pressure H at hub, in excess of vapor pressure = 1.37 ft of water. Slip ratio S = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation indicated is all on the back (suction) side of the blade. Line of the greatest thickness of blade runs from tip to root via midpoint of each section.)

unless the other condition (small N) is met, we must expect all the complications which arise from the fact that thrust and torque will no longer vary as N^2; and the thrust and torque coefficient will become functions of S, N, H instead of simple functions of S.

4—LOCATION OF FIRST BURBLING AND LAMINAR CAVITATION

A LOCALIZED LOW PRESSURE IS PREREQUISITE TO ANY CAVITATION

One of the best methods to eliminate cavitation would be to find the location at which it first occurs and eliminate it there.

A prerequisite to cavitation of any kind is a sufficiently low pressure. This can be demonstrated by experiments such as those reported in section 2G of this paper which show clearly that, all other factors remaining constant, cavitation does not begin until a sufficiently low pressure is reached, that cavitation does begin then, and that it can be crushed out by raising the pressure again. Ackeret's experiments (34) in connection with cavitation erosion show this even more clearly, and specifically show that the pressure required to prevent cavitation is almost exactly that required to prevent boiling.

Cavitation being a localized phenomenon, we may say that a localized pressure, low enough to permit boiling, is a prerequisite to cavitation. As the general static pressure is reduced near the suction face of a working propeller, it is obvious that the region which first reaches a localized pressure low enough to permit boiling is the region which had the lowest pressure before cavitation began. Consequently, if we knew the pressure distribution around a propeller blade, we could point to the region of lowest pressure and say: When cavitation begins it will begin there.

Pressure distribution can be, and has been, determined experimentally on airfoils. There are a number of theoretical methods for predicting with a fair degree of accuracy, the pressure distribution around an airfoil. The experimental method is obviously slow and tedious. The theoretical methods (35), for example the method of sources and sinks, are even more slow and tedious. Since our present object is simply to ascertain approximately where the regions of lowest pressure will occur, it seems possible that shorter and sufficiently accurate methods could be used to estimate this. Since burbling cavitation and laminar cavitation are distinctly different, the study of their sources will be made in separate sections of this paper.

B PROBLEM OF LOCATING FIRST BURBLING CAVITATION BY SHORT METHOD

Burbling cavitation on a blade moving relative to water appears when the pressure in any region has been reduced to approximately vapor pressure, and can be crushed out by increasing the pressure to slightly above vapor pressure, as is shown by the experiments of Ackeret (34). Therefore, the problem of determining the location of the first appearance of burbling cavitation resolves itself into this question: In what region on a propeller blade will the lowest pressure occur?

Since a short method is desired, a number of simplifications will be made, which *a priori* were believed to be justified and *a posteriori* were found to be justified. These simplifications are:

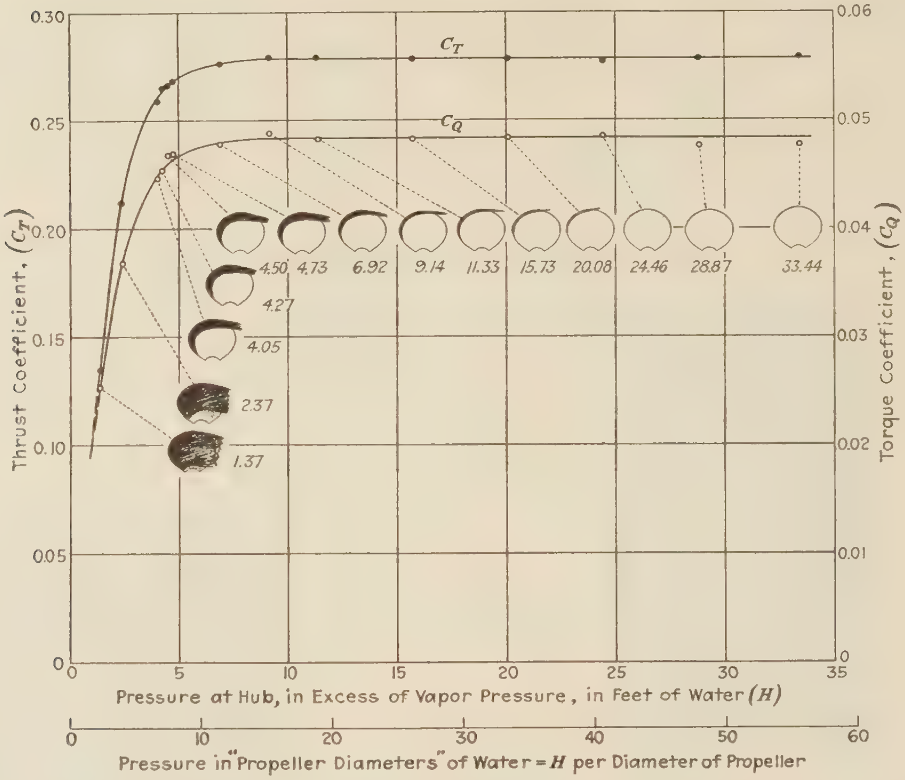

Fig. 12 Curves of C_T and C_Q Versus Pressure H at Hub Propeller 1283-A

(Speed = 1600 rpm. Slip ratio = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation indicated is all on the back (suction) side of the blade.)

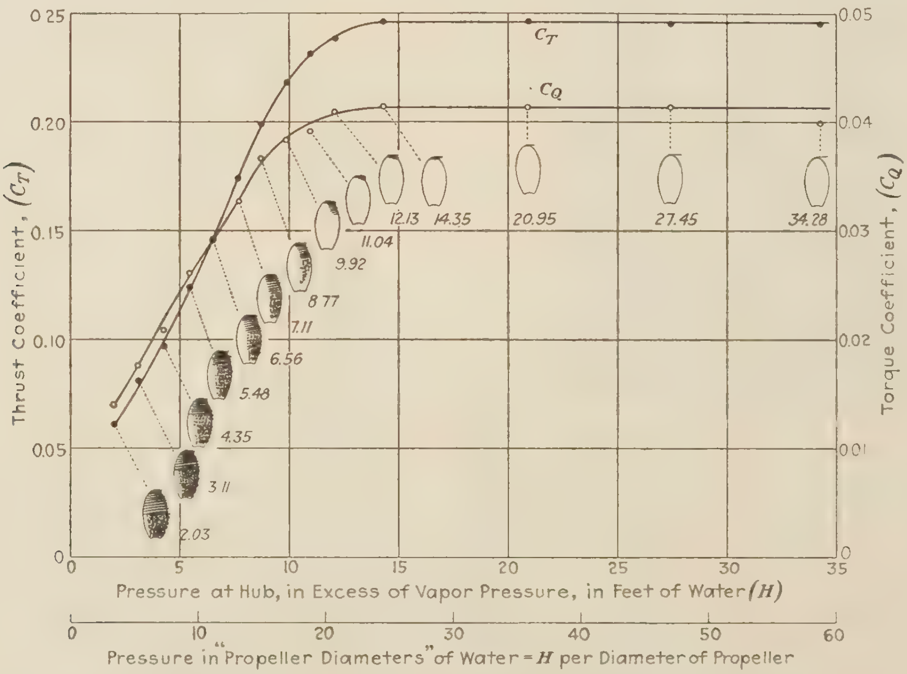

Fig. 13 Curves of C_T and C_Q Versus Pressure H at Hub for Propeller 414

(Speed = 1800 rpm. Slip ratio = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation as indicated is all on the back (suction) side of the blade. Small vortices, shown as streaks, originate at rough spots caused by corrosion after the T-N and Q-N test.)

(*a*) Only the case of uniform motion will be considered.

(*b*) Over the area considered—from near the leading edge to near the trailing edge—the velocity relative to the blade will be considered uniform. (Considering the usual curvature of blade sections and the usual angles of attack, this is a justifiable preliminary simplification and corresponds to that used by Prandtl (27) in deriving the pressure integral over the surface of an airfoil.)

(*c*) Over the area considered the stream lines will be considered approximately parallel to each other.

The following physical statements will be considered as correct for the present purpose:

(*a*) Liquid in which a body is submerged exerts a pressure on it.

(*b*) The pressure can be considered as being exerted by the liquid particles in immediate contact with the approximately stagnant boundary layer of liquid which clings to the body.

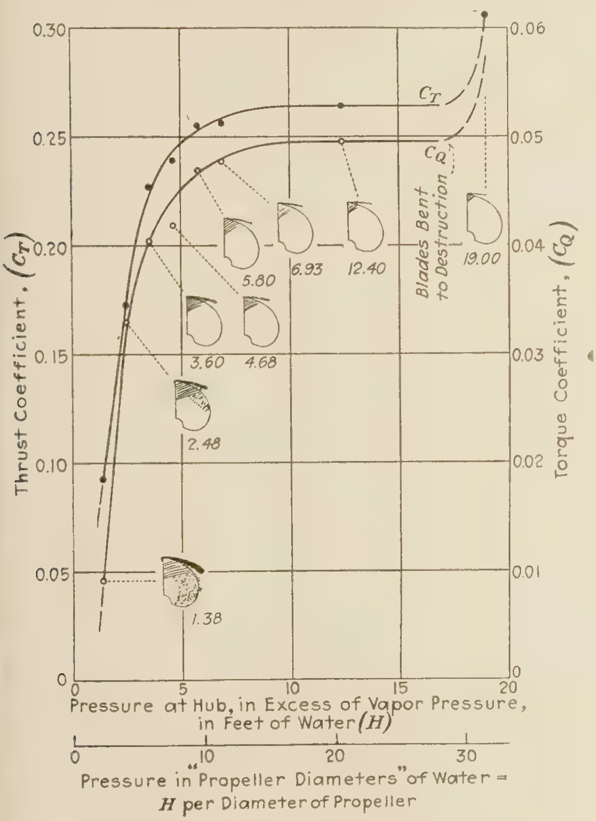

FIG. 14 CURVES OF C_T AND C_Q VERSUS PRESSURE H AT HUB FOR PROPELLER 1538

(Speed = 1600 rpm. Slip ratio = 0.35. Black shading indicates laminar cavitation while dotted shading indicates burbling cavitation. Proportion of blade area covered by cavitation as indicated is probably correct within ±5 per cent. Cavitation as indicated is all on the back (suction) side of the blade. Line of greatest thickness of blade runs from tip to root via midpoint of each section.)

(*c*) The particles outside those mentioned in (*b*) merely increase or decrease the pressure on the latter and, if the stream lines are approximately parallel, do not change the relative pressure exerted by a particle in contact with the body (or boundary layer) as it flows past the body.

(*d*) Consequently, if we determine the relative pressure exerted on a body by a particle which flows past it, but always in contact with it (or the boundary layer), we can determine the location of the lowest pressure.

(*e*) If a particle of liquid is being accelerated, a force is involved.

(*f*) In the case of a submerged propeller blade, the forces of gravity and cohesion can be ignored; therefore, the remaining force is a difference in pressure.

(*g*) A particle of liquid moving relative to but in contact with a submerged body has no relative velocity toward or away from that body, but may be accelerated relatively to the undisturbed fluid and this acceleration may be relatively toward or away from the body.

(*h*) If the acceleration is toward the body, it indicates that the pressure at the body is less than in the surrounding liquid; and vice versa.

C Solution of the Problem

For our analysis of this problem it will be necessary to refer to Fig. 15 and to use for this purpose only the following nomenclature, taking care not to confuse P, S, and N with the values of pressure, slip, and rpm used previously. The distinction between P as a pressure, and P as a point will in every case be perfectly obvious. In Fig. 15 which represents a general cross section of a propeller blade, let

P = a particle of fluid moving relative to but always in contact with the blade

R = radius of curvature of the blade at point P

P_0 = position of P when moving parallel to the direction of the motion of the blade in space, i.e., P_0 is the point of tangency where the curve of the back of the blade is tangent to the direction of motion W, and where $\theta = 0$

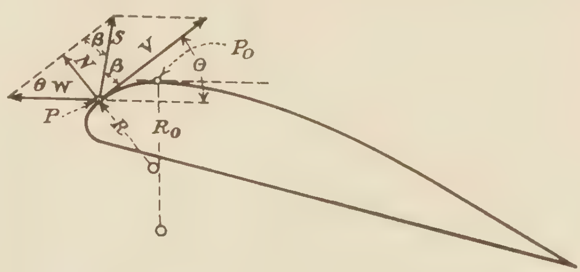

FIG. 15 DETERMINATION OF THE LOCATION OF POINT OF MINIMUM PRESSURE ON A PROPELLER BLADE

R_0 = radius of curvature of the blade at point P_0

W = velocity and direction of the blade in space, i.e., relative to the undisturbed fluid

V = velocity and direction of P relative to the blade. The direction must obviously be tangent to the blade. Note, from Fig. 15, that on the suction side of the blade V must always be greater than W, being compounded of W plus the circulation velocity

S = the velocity of P in space

N = component of S which is normal to the blade

θ = supplement of the angle between V and W

β = angle between S and V

Since V is always greater than W on the suction side, N must always lie between W and S; although, mathematically it would make no difference on which side of S, N lies; for in any case

$$N = S \sin \beta \qquad [19]$$

Now by a law of trigonometry

$$\frac{W}{\sin \beta} = \frac{S}{\sin \theta} \qquad [20]$$

Therefore

$$\sin \beta = \frac{W \sin \theta}{S} \qquad [21]$$

Hence

$$N = W \sin \theta \qquad [22]$$

The rate of change of N with respect to θ is

$$\frac{dN}{d\theta} = W \cos \theta \qquad [23]$$

Now

$$\frac{d\theta}{dt} = \frac{V}{R} \qquad [24]$$

Multiplying Equations [23] and [24] we get

$$\frac{dN}{d\theta} \times \frac{d\theta}{dt} = \frac{dN}{dt} = \frac{WV \cos \theta}{R} \qquad [25]$$

But dN/dt = the component of acceleration in space normal to the blade, so denoting this acceleration by A we have

$$A = \frac{WV \cos \theta}{R} \qquad [26]$$

and we have to consider how the value of A may vary with the position of the point P, when the shape of the blade, the angle of attack, and the speed W are given.

By our simplifying approximation (*b*), in section 4B of this paper, the speed V may be treated as a constant, except close to the edges of the blade; hence we may set

$$\frac{WV}{R_0} = C = \text{a const} \qquad [27]$$

and, letting $R = mR_0$ we may write Equation [26] in the form

$$A = C \frac{\cos \theta}{m} \qquad [28]$$

We exclude from consideration, as not occurring in marine propellers, those profiles in which the suction face is concave near the trailing edge; and consequently m is then always positive, varying from a small fraction near the leading edge of an airfoil section such as that illustrated by the figure, to $+ \infty$ at a place where the blade is flat. The angle θ is positive on the leading part of the blade, ahead of P_0, and negative on the trailing part, but always between + 90 deg and—90 deg so that $0 \gtreqless \cos \theta \gtreqless 1$; hence, A can never become negative.

"Ogival blades" are blades in which the profile of the back is a circular arc. These are the easiest to discuss for $m = 1$ everywhere, so that Equation [28] reduces to

$$A = C \cos \theta \qquad [29]$$

The value of A is evidently a maximum for $\theta = 0$, i.e., at the point of tangency P_0, and falls off in both directions so long as V remains constant.

Therefore, in the case of ogival blades burbling cavitation will ordinarily begin at the point of tangency, P_0. It is to be noted that the location of P_0 depends on the angle of attack, which is about half the slip angle due to the increase of water speed ahead of the propeller.[7] As the slip ratio increases, P_0 approaches and ultimately reaches the leading edge, where it can no longer be assumed that V = a constant; and in such case Equation [29] must be replaced by

$$A = \frac{WV}{R} \cos \theta \qquad [30]$$

As P (not P_0) approaches the leading edge, cos θ continues to decrease (slowly if the blade is thin); but if V increases rapidly, A may have another maximum which may be higher than the one at P_0. Now physical common sense and Bernoulli's theorem indicate that at high angles of attack[8] there will probably be a great local increase of V near the leading edge. Right at the leading edge $\cos \theta = 0$, so it is to be expected that if there is a maximum of A near the edge it will not be right at the edge although close to it; which is what actually happens, as will be indicated later.

Hence, in regard to ogival blades we may say:

(*a*) Under ordinary conditions of operation and at ordinary slip ratios there will be only one maximum value of A that it will be at the point of tangency P_0, and burbling cavitation will start there.

(*b*) At higher slip ratios there may be two maximum values of A: One at P_0, and the other sharply localized near the leading edge, and burbling cavitation may start independently from both places and finally spread and come together as W increases or the pressure is lowered.

(*c*) At high slip ratios, and angles of attack, P_0 will be at or so close to the leading edge that even if there were two maximum values of A at lower slip ratios the two would coalesce and burbling will start at or very near the leading edge.

Blades of "airfoil section," so far as they occur in marine propellers, have backs (suction faces) with a radius of curvature that is very small near the leading edge and increases continuously toward the trailing edge so that from P_0 forward $m < 1$ and from P aft to the trailing edge $m > 1$.

Near the trailing edge, and with such slips as occur in practice, θ is a rather small negative angle and cos θ is a little less than unity. As the point P moves forward cos θ passes through its maximum value of unity (i.e., $\cos \theta = 1$ at P_0) and then decreases more and more rapidly as P approaches the leading edge.

Since, in practice, between P_0 and the trailing edge $\cos \theta < 1$ and $m > 1$, the maximum value of A will not occur behind, but will occur at or forward of P_0.

Hence, we need to discuss only that portion of the blade from P_0 forward. Referring to Equation [28], it will be seen that the ratio ($\cos \theta/m$) is the controlling factor. Since both cos θ and m decrease as P moves forward from P_0, the value of the ratio ($\cos \theta/m$) will depend upon the respective rates of their decrease. Several practical cases may be cited:

(*a*) The ratio ($\cos \theta/m$) may vary at such a rate that as P moves forward A increases from its value at P_0 up to some greater value and then decreases; this is the usual case for airfoil sections, and in such a case burbling cavitation would begin forward of the point of tangency P_0.

(*b*) The ratio ($\cos \theta/m$) may vary at such a rate as P moves forward that A remains constant up to some point and then either increases or decreases. In the former case burbling cavitation would start so far forward of the point of tangency P_0 as to occur near the leading edge and in the latter case would start simultane-

[7] Aside from theoretical considerations, this increase of water speed ahead of the propeller can be proved by examination of the stream lines in the illustrations, particularly Fig. 10, of the paper "Photographs of the Flow Round a Model Screw Working in Water, Especially in the Vortex Ring State," by C. N. H. Lock and H. C. Townsend, *Philosophical Magazine and Journal of Science*, vol. 3, series 7, January-June, 1927, p. 224. In order to photograph the flow, Lock and Townsend sprayed into the water a mixture of xylene and carbon tetrachloride which has a density about equal to that of water but has a different refractive index.

[8] In the case of a marine propeller, an angle of attack in the order of 5 deg or greater must be considered high since it corresponds to a slip ratio so high that it is practically impossible for a propeller to operate satisfactorily. For example, if the angle of attack is 5 deg, the slip angle is about 10 deg, and if the pitch ratio is 1.0, the slip ratio will be 0.578, or nearly 58 per cent. Operating steadily at such a slip ratio is not practical because the maximum efficiency of propellers occurs at slip ratios of about 0.15 to 0.20.

ously over an area which is forward of the point of tangency.

(c) The ratio ($\cos\theta / m$) may vary at such a rate that there are two or more maxima, but this is unusual except in the case of high slip ratios where both maxima are so close to the leading edge that for practical purposes they coalesce, and as in the case of ogival blades at similar high angles of attack burbling cavitation would start in close proximity to, but not right at, the leading edge.

In view of the foregoing discussion it may be stated that under usual conditions burbling cavitation on an airfoil blade will start forward of the point of tangency P_0.

This discussion suggests that we should use the smallest radius of curvature of the back of the blade that can be used, while keeping out of burbling cavitation. Also, that we should so vary the radius of curvature that when burbling cavitation does occur it will occur simultaneously over the greatest possible area, for in such a case we shall have been exerting the maximum possible suction over the greatest possible area.

Equation [26] and Equation [30] indicate an explanation of the well-known fact that for a given width of blade the greater the thickness (and consequently the less the radius of curvature) the greater the lift (23, 36)—up to the point of burbling cavitation.

Since we were interested only in the reduction of pressure which causes burbling cavitation, the foregoing discussion was limited to the back of the blade, as under ordinary conditions the reduction of pressure occurs only on the back. However, at very small, or negative angles of attack reduction of pressure can occur on the face of the blade. The essential condition for reduction of pressure is that a particle P, flowing in contact with the blade, is being accelerated toward the blade. For such acceleration to occur the vector V shown in Fig. 15 must swing toward the blade as P moves toward the trailing edge. When the angle of attack is so low that the stagnation point[9] is on the back of the blade, the water which flows around the leading edge to the face of the blade must be accelerated toward the blade in that region and hence cause a reduction of pressure. Consequently, there may be a maximum reduction of pressure on the back of the blade and another on the face of the blade. This condition is shown later in Fig. 16 for angle of attack = −6 deg.

Although, in so far as cavitation is concerned, we are not concerned with increase of pressure, yet it should be pointed out that arguments similar to those which lead to the derivation of Equation [28] indicate an explanation of the well-known fact that the flat pressure face of a blade contributes a relatively small proportion to the thrust of a propeller (or lift of an airplane wing) in comparison to the thrust contributed by the suction side of the blade. At ordinary angles of attack the stagnation point is on the pressure side of the blade. The particles which flow in contact with the blade must have passed the immediate vicinity of the stagnation point. At that point the velocity component normal to and toward the blade is reduced to zero and consequently the acceleration normal to and away from the blade is a maximum, and there the highest pressure will occur. Thereafter, if the blade is flat, particles flowing in contact with it would have no acceleration normal to it and consequently would not increase the pressure. Such increase of pressure as does occur behind the stagnation point must be attributed to the slowing of the flow of water, and to particles not in contact with the blade which are still changing their velocity normal to the blade after the leading edge has passed. On this basis, if the pressure face of a blade is concave, a particle flowing in contact with it would be accelerated away from the blade during its passage across the blade and we could expect a greater pressure on the face; which does occur as matter of experimental fact.

[9] The stagnation point on the blade is where the stream of water divides, part flowing around the back and part flowing around the face.

D Experimental Verification

A number of ogival blades were tested at various angles of attack, and the pressure distributions are given in Report No. 499 of the Construction Department, Navy Yard, Washington, D. C., July 29, 1933. In every case there is a maximum suction very close to the point of tangency (where $\theta = 0$). The agreement is so close that any departure therefrom may well be an error of observation, considering that the measurements are taken at a number of points on the back of the blade and a curve faired through them. The only complication which arises is when the blades are at a high angle of attack (above 5 deg); this complication was indicated in the discussion of the Equation [30]. The complication is that there are two maxima. The first is due to flow around the sharp leading edge where R approaches 0. This gives a strictly localized and high degree of suction near the leading edge (within about 5 per cent of the chord length from the leading edge). The suction then decreases sharply, and thereafter rises to the normal maximum at the point of tangency (where $\theta = 0$).

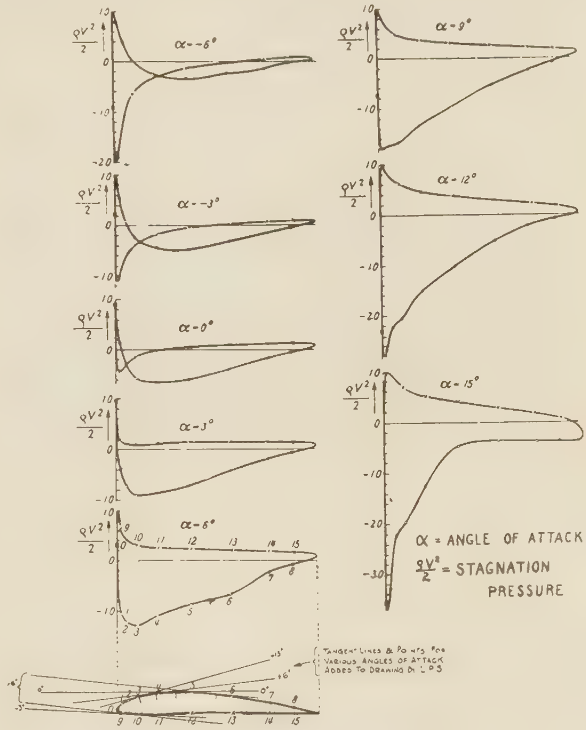

Fig. 16 Pressure-Distribution Curves for Middle Section of an Airfoil at Various Angles of Attack

(The curves reproduced here are from Prandtl (29). Notice that in every case the point of lowest pressure (maximum suction) is forward of the point of tangency, and that the more rapidly the radius of curvature is decreasing forward of the point of tangency, the further forward, relatively, is the point of lowest pressure. Notice particularly the case of $\alpha = -6$ deg where there is a point of lowest pressure on the upper side and the lower side of the wing.)

In the Report No. 34 of the Construction Department, Navy Yard, Washington, D. C., July 7, 1917, there are given the experimentally determined pressure distributions for an airfoil blade at a number of angles of attack and modified a number of times as to shape by bending the trailing edge. An examination of these shows the same general law to hold; the lowest pressure is near the point of tangency (where $\theta = 0$); or more generally forward of that if R is decreasing rapidly.

Prandtl (29) shows the experimentally determined pressure-distribution curves for the middle section of an airfoil at various

angles of attack. Those curves are reproduced in Fig. 16 with the addition of lines of tangency for the various angles of attack drawn on the sketch of the airfoil section. It will be seen that the lowest pressure occurs forward of the point of tangency (where $\theta = 0$) for each angle of attack and that R is decreasing rapidly forward of the point of tangency.

The tests of over 50 model propellers have been carried through cavitation. In every single case burbling began, as nearly as could be estimated, at the point of tangency, i.e., where $\theta = 0$, in accordance with the formula derived above; or somewhat forward of that point in the case of airfoil sections which have R decreasing toward the leading edge.

An important caution to observers should be noted at this point: The bubbles form, drift toward the trailing edge, enlarge, and collapse; therefore, the center of the area in which they are seen is well behind the point of initial formation. Obviously, the bubbles must begin forming at least as far forward as the leading edge of the area in which they are seen. At first glance, the leading edge of this area will not be seen as far forward as it really is because the illumination by a stroboscope is dim and the very small bubbles cannot be seen at their initial formation. Therefore, an observer should allow ample time for his eyes to become fully accommodated to the dim illumination of the stroboscope, concentrate attention on the leading edge of the burbling cavitation field in order to determine where burbling actually begins, and then raise and lower pressure to crush the cavities and then permit them to re-form. It will be well worth while for an observer to familiarize himself with the "still" reproductions of Mueller's (37) slow-motion pictures of burbling cavitation on a fixed blade in order to be certain of the details he should watch for on a rotating propeller.

E Usefulness of Equation [30]

As shown in the foregoing discussion, the acceleration dN/dt is the result of a pressure at the blade above or below that of the surrounding fluid. The total pressure at the blade is the pressure of the surrounding fluid plus or minus this acceleration pressure. Whether or not burbling occurs depends upon the total pressure at the blade. Hence, if the pressure in the surrounding liquid can be raised sufficiently, burbling cavitation can be crushed out. (See the author's variable-pressure experiments reported in section 2G of this paper.)

But the pressure on a marine propeller is limited by its practicable submergence. In the case of a surface ship the absolute pressure at the hub is limited to a fairly narrow range. As shown in part 3 of this paper, this pressure is about equal to that of a column of fresh water (3.7 ± 0.7) times the propeller diameter. Therefore, if the propeller is submerged as far as practicable, relief from burbling must be sought elsewhere. Equation [30] shows this can be done in three ways; viz.,

(*a*) Decrease W, which means decrease the speed of the propeller, particularly its rotary speed.

(*b*) Decrease V, which is compounded of W and the circulation velocity. Consequently, V can be reduced by decreasing either W or the speed of circulation, or both. The speed of circulation can be reduced by decreasing the angle of attack, i.e., the slip ratio in the case of a propeller.

(*c*) Decrease $(d\theta/dt)$. This can be done by increasing the radius of curvature of the blade, even though V remains constant. This increase of curvature can be attained by either widening or thinning the blade, or both.

As an important caution, Equation [30] indicates with a tolerable degree of accuracy where the point of lowest pressure occurs, and consequently where burbling cavitation starts. It is not intended to, and does not, predict the pressure distribution over the entire blade. The simplifying assumptions that from near the leading to near the trailing edge of a blade the velocities are uniform, and the stream lines parallel, are not nearly accurate enough for that. Consequently, while the formula may be used for estimating where burbling cavitation will first occur and what should be done to delay the occurrence, it should not be used for estimating actual pressure distribution more than a short distance in either direction from the point of maximum acceleration.

F A Vortex Is Prerequisite to Laminar Cavitation

A laminar cavity is a cavity stretched out in a long thin sheet or tube. A little consideration of the operation of the forces of hydrostatic and hydrodynamic pressures of liquids and gases, and the force of surface tension, will be convincing that a cavity in a liquid—in other words a bubble—must assume a form that is roughly spherical if the cavity is floating freely, and roughly hemispherical if the cavity is in contact with a solid unless some additional force is acting. A burbling cavitation field may have any form, but the individual bubbles will be of the forms indicated.

On the other hand, at the axis of a tubular eddy or vortex, the pressure falls below the static pressure in the body of the liquid outside because of the centrifugal forces of rotation, and if it falls as far as to the vapor pressure of the liquid, a tubular cavity is formed. The liquid tends to boil off into this open space, but any foam or spray that may result will also be rotating and will be thrown out against the walls of the cavity, frequently leaving an optically empty core with sharply defined walls. It is not apparent that an elongated cavity with this clear-cut appearance, characteristic of laminar cavitation, could originate from any other cause, and therefore the following argument will proceed on the assumption that the formation of a tubular vortex is prerequisite to the occurrence of laminar cavitation.

G Location of First Laminar Cavitation by Vortex Generators

If vortex formation is necessary for laminar cavitation, it may be expected that this cavitation will begin at such points on the blade as are most likely to generate strong vortices. Such parts of a blade will be called, for convenience, "vortex generators." The problem of locating the first laminar cavitation then resolves itself into locating vortex generators.

Ample theoretical and experimental authority for the immediately following discussion of vortex generators can be found in the works of Prandtl (30, 38) from which several quotations will be made. To simplify the discussion, the example of a single airplane wing will be discussed first, and the results applied to propeller blades later.

In the case of a finite wing the pressure differences between the top and bottom have "to disappear gradually toward the wing tips. On account of the greater pressure below the wing surface than above it, some air will flow from the bottom to the top around the wing tips. Therefore a sidewise current exists over most of the wing surface," directed outward on the lower side and inward on the upper side. "This causes a surface of discontinuity in the air leaving the wing, which is ultimately rolled up into two distinct vortices. According to the theorem of Helmholtz, these vortices always consist of the same air particles so that they leave the wing approximately with the wing's velocity through the air."

The term "bound vortex" has been reserved by many writers for the theoretical lifting vortex around and traveling with the wing. The term "free vortex" is generally applied to those actual vortices which trail astern from the wing tips, and it is a very appropriate name considering that the particles of fluid actually flow away from, or are left behind the wing.

But, desiring to bring out another idea, the author has coined the term "anchored vortex" in order to connote the idea that what-

ever the particles may be doing the form of the vortex remains anchored relative to the wing. The "sidewise current" mentioned previously makes the particles move in approximate helixes around the core of the vortex, making the vortex itself (when rendered visible by any means) take on the appearance of a twisted ribbon. Since new particles are continually being fed into the vortex, this helical motion around the core is necessary to the continued existence of an anchored vortex. If, instead of a helical motion, the particles had a motion in closed circuits around the core, the vortex could not possibly remain anchored. It would break away from the wing and drift astern, to be followed by a succession of other similar vortices; producing the phenomenon known as the Kármán Trail.

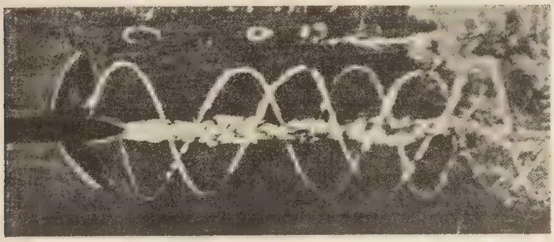

FIG. 17 ILLUSTRATING THE POSSIBILITY OF ROOT VORTICES AS WELL AS TIP VORTICES

The tip of a propeller blade corresponds to the tips of a wing. Therefore, it may be expected that the tip of a propeller blade will be the major vortex generator. If root vortices exist they are rarely apparent as cavities trailing astern, but the possibility that they may exist and can form cavities is indicated in Fig. 17, the illustration of which is credited to Flamm (49).

It may be readily understood that, by reason of the sidewise current, the tip vortex will start at some radius well short of the actual tip radius if the leading edge is curved aft, as is usual with propeller blades. This, in fact, does occur, and the straighter the leading edge the further toward the tip does the actual vortex start.

Obviously, any nick, roughness, or other irregularity on the blade will cause some disturbance of the flow over the surface of the blade. If the form of the irregularity is such as to produce a sidewise current the irregularity becomes a miniature vortex generator, and a miniature anchored vortex is formed. A group of such miniature anchored vortices is a laminar cavitation field.

(*H*) EXPERIMENTAL VERIFICATION BY DIRECT OBSERVATION

Typical examples of laminar-cavitation fields are indicated in Fig. 13 showing the cavitation characteristics of model propeller No. 414 after it had corroded and become roughened, and in Figs. 11 and 14 showing the cavitation characteristics of model propeller No. 1538 which had a weak leading edge easily subject to deformation. This latter propeller had a large anchored vortex originating almost exactly at the tip; on lesser radii it had a series of minute vortices. In every case the rough spots generating the minute vortices could be located by feeling with the finger nail or by observation with a magnifying glass. That there were separate minute vortices could be seen by lowering and raising the pressure so that the cavities formed and disappeared. With advanced stages of cavitation at very low pressures the edges of the thread-like tubular cavities were so close to each other that it was difficult to see clearly that they were separate; hence the impression was sometimes given that the cavitation field was a single thin sheet of one cavity. However, occasional clear glimpses showed that the thin sheet was composed of a series of thread-like tubes closely packed side by side, and slightly raising the pressure made it apparent that there really were a series of miniature anchored vortices forming the laminar-cavitation field.

It is much simpler to obtain direct observation of the large laminar cavities produced by tip vortices. The usual view of them is with the line of sight almost normal to the blade. With this view they give the appearance of thin sheet-like and perfectly smooth cavities lying on the back of the blade as shown in Fig. 5. There is no "ribbed" appearance to the sheet such as marks the separate minute vortices in a laminar-cavitation field. From the point of view described previously it is hard for an observer to see that the cavity really is the core of a vortex as long as he is looking through it at the blade, although he might infer this by looking at the "twisted-ribbon" shape, typical of an anchored vortex which trails away from each tip. But, if the observer moves so that his line of sight is practically tangent to the back of the blade, it is apparent that this "twisted-ribbon" or tubular cavity, shown in Fig. 18, forms the whole of the laminar cavity. Owing to the structure of the variable-pressure water tunnel it is difficult to get into position to obtain these latter views, which is probably the reason they were not observed before. The author would not have made observations from such a point had he not been led by *a priori* theoretical considerations to assume that a vortex is prerequisite to laminar cavitation, and then to try observing laminar cavities from all possible situations in order to find out if the assumption were true. The actual view with the eye is much clearer than the photograph. The stroboscopic light is so dim that the exposure of the photograph had to be about 10 revolutions, thus blurring the sharpness and distinctness of the edges of the cavities and not showing the actual helical motion of the water around the cavity which can be seen by an eye accustomed to the dim light.

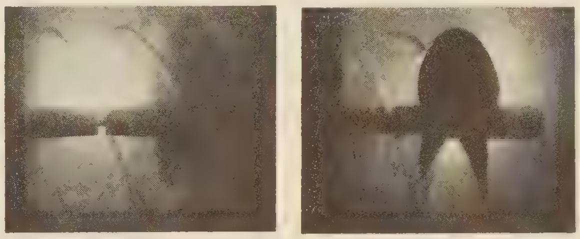

FIG. 18 PROPELLER 1283-*A* OPERATING AT 1600 RPM WITH 35 PER CENT SLIP

((*a*) Pressure at hub, in excess of vapor pressure = 8.66 ft of water. View is from such an angle that line of sight is approximately tangent to the back of one blade. The laminar cavity is not in contact with the back of the blade, but is separated therefrom by a thin wall of water. This is also true of (*b*) which was taken with a water pressure, in excess of vapor pressure, of 7.30 ft of water.)

The process of formation of a laminar cavity can be observed extraordinarily well by the following special procedure: Run the propeller at constant speed and slip as when taking the *T-H* and *Q-H* curves, start with full atmospheric pressure on the water surface, and pump down toward vacuum as rapidly as possible. The tip vortices, with their centers of low pressure have been there all along, of course, but cannot be seen because there is no appreciable difference in refractive index between the high- and low-pressure regions. As soon as cavity starts, there is a sharp difference in refractive index and the cavity is clearly visible. Following the procedure outlined, the observer sees the following successive phenomena: A series of small bubbles—like glass beads on a string—form along the axis of the vortex at a slight distance away from the blade. These bubbles enlarge and elongate until they appear like a string of sausages. With still further reduction of pressure, the ends of the bubbles coalesce and the typical laminar cavity results—a long tubular bubble, which has a cross section approximately circular while the diameter is small, and a

cross section becoming more and more elliptical as the diameter enlarges near the blade. The bubble with an elliptical cross section trails away from the blade like a twisted ribbon. As the laminar cavity collapses well astern of the propeller it goes through the reverse process: Its cross section becomes more circular, parts of the wall collapse giving it the appearance of sausages again, and finally the string-of-beads state is reached just before the final collapse. In the collapse of a very large laminar cavity these processes cannot all be seen so clearly, as the "string-of-sausages" state and string-of-beads state are more likely to be churned into turbulent foam owing to the larger forces involved.

In every case, however, as long as conditions permit clear vision and the line of sight is nearly tangent to the blade, it is apparent that the laminar cavity itself is not in contact with the blade; rather, it is always separated from the blade by a layer of water, sometimes a thin layer, but, nevertheless, a definite layer of

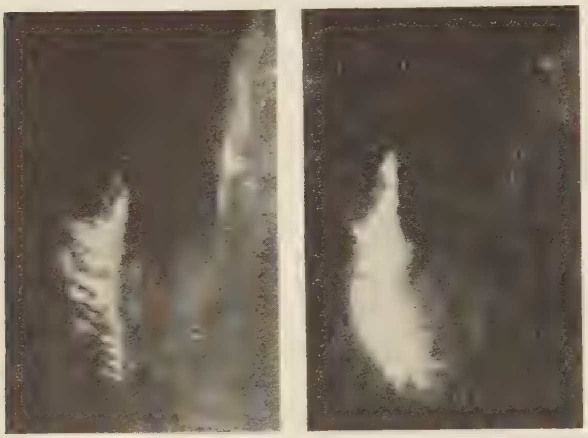

Fig. 19 Typical Examples of a Frothy Burbling Cavitation Field

(This cavitation field occurs when the water flows over a sharp leading edge in such a manner that no sidewise current exists, and consequently water cannot travel in approximately a helical path around a central axis, thereby forming an anchored vortex. These illustrations show face cavitation on the pressure side of the leading edge of a blade at low slip ratios. Illustrations published through the courtesy of the Institution of Naval Architects, London.)

water. An examination of Fig. 18 with a magnifying glass will show this. Some illustrations by Lerbs (40) of the cavitation around a stationary blade also show this effect. Study of the question will indicate that if, as assumed, a laminar cavity is at the core of a liquid vortex, then the cavity itself cannot possibly be in contact with the blade, because a vortex could not exist with one wall solid. This point is very important in explaining propeller action during cavitation; and will be discussed later in part 5 of this paper.

When flow around a sharp edge has no sidewise current, and consequently cannot produce an anchored vortex, a laminar cavity does not result. Instead, a burbling cavitation field is produced and is filled with frothy foam as shown in Fig. 19. This is typical of cavitation which occurs near the leading edge of the pressure face of a blade when the propeller is operating at a low slip ratio, or having some portion of the blade operating at very low or negative angle of attack. The hypotheses regarding vortex generators developed in the two preceding sections offer a practical explanation of the known facts that laminar cavitation can be reduced or delayed by (*a*) making the blade perfectly smooth and with easy curves, particularly near the leading edge; and (*b*) in particular by reducing the pitch near the blade tips, which, of course, reduces the sidewise current there and consequently reduces the strength of the anchored vortex at the tips.

I Experimental Verification for Both Kinds of Cavitation From Test Records of Numerous Propellers

In the foregoing sections there have been developed certain hypotheses regarding where burbling and laminar cavitation will begin. These hypotheses were developed by *a priori* reasoning from known physical laws and verified by intensive experimentation by the author on three types of propellers and by experimental evidence from known pressure distribution and vortex action on various types of airfoils.

Not being satisfied to stop at this point the author searched the records of the U. S. Experimental Model Basin for all propellers which had cavitation characteristics recorded. He examined these records to find if any one observation was contrary to his hypotheses, because one such observation would overthrow them. There was not one observation contrary to the hypotheses.

5—THE REASONS CAVITATION REDUCES THRUST AND TORQUE

A Rejected Explanations

An extensive study of the literature regarding marine propellers has revealed many writers and experimenters who state or prove that cavitation reduces thrust and torque below that which would be obtained with all other conditions the same except the existence of cavitation.

The favorite explanation of this phenomenon can be summarized in the words of Tutin (41):

"The thrust of a screw propeller is the resultant longitudinal component of the excess pressure on the face of the blades and the defect of pressure on the back. Both the pressure on the face and the suction on the back increase as the speed of advance and the revolutions are increased, but whereas an excess pressure may go on increasing indefinitely, the limit of suction at a given point is reached when the absolute pressure is reduced to zero, assuming for the moment an ideal fluid which does not evaporate, and which contains no occluded gases. Any further increase in speed and revolutions will produce no further increase in thrust at this point, and, will merely extend the boundaries of the region over which the pressure is zero.

"In the case of a fluid which evaporates, the limit of pressure will be reached when the absolute pressure is equal to the vapour pressure."

Other writers use similar explanations (15, 23, 42).

The implications of this explanation can be studied more readily if thrown into the form of mathematical equations. Remembering that the thrust is only one component of the total force, or lift, acting on an inclined plane moving through water, then

$$L = (h + p) - (h - s) \quad [31]$$

where L = lift on the inclined hydrofoil (or propeller blade); h = force on one whole face of the blade due to static pressure in excess of vapor pressure; p = force in excess of h due to kinetic action[10] on the entire pressure face; and s = amount by which force on the suction face is reduced below h by kinetic action.

It is further assumed (see last two sentences of the foregoing quotation from Tutin) that variations of h or s can carry $(h - s)$ down to a minimum of 0 when cavitation will occur; and that further variation in the same direction will leave $(h - s)$ constant. Hence according to the explanation:

When $(h - s) > 0$

$$\frac{\partial L}{\partial h} = 0 \quad [32]$$

[10] The term "kinetic action" is used purposely rather than "dynamic action" because it is more accurate and because of explanations in subsequent sections of this paper.

When $(h - s)$ is 0 and constant

$$\frac{\partial L}{\partial h} = 1 \qquad [33]$$

The implications of Equation [32] may be accepted, for it is a matter of general experimental fact that there is little or no variation of lift with pressure alone before cavitation occurs. The implications of Equation [33] may be accepted provisionally for certainly after cavitation occurs the lift decreases rapidly with pressure (although, for reasons which will not be discussed in this paper, it is doubted that the variation follows such a simple law as that indicated in Equation [33]).

The favorite explanation further assumes that, all other conditions (such as angle of attack, shape and size of blade) being constant

$$p = k_1v^2 \qquad [34]$$

and

$$s = k_2v^2 \qquad [35]$$

where k_1 and k_2 = constants for the particular conditions; and v = velocity relative to the undisturbed fluid.

Now, for a given propeller with a fixed pitch and operating at a fixed slip ratio we could substitute N (the rotary speed) for v and use other constants so that Equations [34] and [35] become

$$p = k_3N^2 \qquad [36]$$

and

$$s = k_4N^2 \qquad [37]$$

Substituting these values in Equation [31] we obtain

$$L = (h + k_3N^2) - (h - k_4N^2) \qquad [38]$$

and therefore when $(h - s) > 0$

$$\frac{\partial L}{\partial N} = (k_3 + k_4) \times 2N \qquad [39]$$

and when $(h - s)$ is 0 and constant

$$\frac{\partial L}{\partial N} = k_3 \times 2N \qquad [40]$$

The clear implications of Equations [39] and [40] are that both in and out of cavitation $\partial L/\partial N$ is always positive and greater than 0; although under cavitation conditions $\partial L/\partial N$ is smaller than under noncavitation conditions.

Since the forces producing thrust T and torque Q are merely components of L (corrected for skin friction) the implications of Equations [39] and [40] apply likewise to thrust and torque, so that the favorite explanation implies that both $\partial T/\partial N$ and $\partial Q/\partial N$ are always positive and greater than 0, although reduced under cavitating conditions.

It has been shown elsewhere (43) that if other things were equal the standard theories of propeller action all implied that

$$T = CN^m \qquad [41]$$

where T = thrust; C = a constant; N = revolutions per unit time; and m = a positive constant exponent, usually taken as 2, but always positive.

Therefore, the standard theories of propeller action imply that

$$\frac{\partial T}{\partial N} = mCN^{m-1} \qquad [42]$$

Equation [42] has the same form as Equations [39] and [40], which merely means that the favorite explanation of the action of propellers in cavitation follows the same form as the standard theories of propellers not in cavitation. The only difference is that the constant C would not be the same under cavitating conditions as the constant which is used under noncavitating conditions.

Without exception, every formally expressed theory the author has read or heard of contains these implications of Equations [39] and [40]. Notice that the value of $\partial L/\partial N$ being less in Equation [40] than in Equation [39], it is proper under the implications to state the frequently used expression "the thrust or torque decreased with increasing N due to cavitation" provided we keep in mind an implied qualifying clause necessary to make the statement precise, viz., "below the values which would have been obtained without cavitation."

Notice further that under the explanation so far given it would never be permissible to leave out that qualifying clause and boldly state: "the thrust and torque decreased with increasing N," for this would imply that $\partial T/\partial N$ and $\partial Q/\partial N$ could sometimes have zero and negative values. But the T-N and Q-N curves discussed in section 2F of this paper show that such zero and negative values do actually occur. Therefore, an explanation which implies that they cannot occur must contain an error.

It is highly improbable that this error in explanation could have persisted so long through the works of so many eminent writers had it not been for the almost universal habit of plotting propeller data in the form of thrust and torque coefficients (C_T and C_Q) over slip ratio S. Such coefficients, valuable as they are, often prevent a clear apprehension of just what variations in thrust and torque are occurring, and plotting them only over S is very effective in concealing variations which occur with changes of N. Similar difficulties can arise from the habit of plotting the so-called "polar curves" of coefficients with slip ratio or angle of attack written in as parameters. A further practice of plotting some dimensionless coefficient against Reynolds' numbers, while useful in summarizing great masses of data, is almost equally effective in making it difficult to apprehend the actual variations which are occurring in the important units of measurement. It is for these reasons that the author has made such extensive use of plotting actual values of thrust and torque, and of plotting them over actual values, not only of slip ratio but also of rotary speed and of pressure.

In spite of this, it is believed that a few writers have recognized that T and Q can actually decrease with increasing N, although recognition of that fact did not appear in their formal explanations. For example, both Saunders (11) and Baker (24) hint that the effects of cavitation are caused by a change in the "effective blade shape" or camber. Now the only way in which a cavity could change the camber of the blade would be to increase it, i.e., make the blade thicker. It has been shown repeatedly (28, 36) that increasing the camber (which involves increasing the thickness of the blade and decreasing the radius of curvature of its back) reduces efficiency but increases the lift. Therefore, the only change in effective camber which cavitation might make would be to increase it, and while this might be expected to reduce efficiency (which actually happens in cavitation), it could not reduce the thrust and torque (which also actually happens in cavitation). If it did anything, it would increase the lift and consequently thrust and torque. Walchner (4) even states that at the very beginning of a cavity on the back near the leading edge he can detect a slight increase of lift, although a decrease occurs later. Therefore the suggestion that a cavity causes a change in effective camber and that this causes a reduction in thrust and torque must be rejected as an explanation.

In oral discussions, the suggestion has been made to the author that boundary layer action might account for decreased lift with increased speed. Jacobs (44) shows that for an airfoil moving through air at low Reynolds' numbers the "point of separation"

between "dead air" in the boundary layer and the flowing air creeps forward from the trailing edge as the Reynolds number increases, and consequently reduces the maximum-lift coefficient below the value it would have had if such boundary-layer action had not occurred. He further shows that with still further increase of Reynolds' numbers, turbulence sets in, sweeps away part of the "dead air," and from then on the maximum-lift coefficient increases with increasing Reynolds' numbers. With the same wing operating in the same medium the changes of Reynolds' numbers would be directly proportional to changes of velocity and hence the changes in lift coefficient would vary with velocity in the same manner that they vary with Reynolds' numbers. It is not clear from Jacobs' paper that the lift itself ever actually decreased as velocity increased in the manner that thrust and torque decrease in the case of a cavitating propeller.

However, Prandtl (31) gives experimental evidence that the drag on a sphere or cylinder moving through a fluid increases with increasing velocity to a critical point, then decreases with further increased velocity, and finally increases again at a slower rate with still further increases of velocity. Prandtl explains this action satisfactorily by the boundary-layer theory. Now the shape of this drag-velocity curve is so similar to the shape of the *T-N* and *Q-N* curves that it seems plausible to explain the latter by the same boundary-layer theory—until the matter is examined more closely.

First, in the phenomenon described by Prandtl (31) the inflection in the drag-velocity curve, for a particular object and a particular fluid, occurs at a definite velocity without regard to pressure so long as that does not affect the kinematic viscosity of the fluid. In the case of the *T-N* and *Q-N* curves the inflection occurs at a different velocity for every different pressure, and with sufficient pressure it disappears entirely.

Second, the disturbance in the boundary layer always begins at the trailing edge and works forward with increasing velocity, until turbulence wipes it off in part. The disturbance due to cavitation never begins at the trailing edge and increasing velocities do not reduce it.

It should be noted most emphatically that all effects arising in the boundary layer are caused by loss of kinetic energy, i.e., decreased velocity with resulting stagnation and eventually turbulence. The remedies are either to suck the troublesome boundary layer into the solid, or to supply the boundary layer with additional kinetic energy, i.e., to increase its velocity.

On the other hand, the troubles due to cavitation are not due to stagnation or too low a velocity but always occur in connection with too high a velocity at too low a pressure. Cavitation results from causes other than and radically different from those that cause a turbulent boundary layer.

For these reasons we must reject the explanation that cavitation phenomena are due to action in the boundary layer.

In searching for another possible explanation let F_1 = total force due to absolute pressure on pressure side of blade; F_2 = total force due to absolute pressure on suction side of blade; and F_0 = total force which would exist on suction side of blade if F_2 were due only to vapor pressure.

Then Equations [31] and [38], which express the "favorite explanation" could be written as

$$L = F_1 - F_2 \qquad [43]$$

This statement is obviously true. Since erroneous results are obtained by using it, an examination of the assumptions regarding F_1 and F_2 is indicated. Referring to Equations [31], [34], and [36]

$$F_1 = (h + p) = (h + k_1v^2) = (h + k_3N^2) \qquad [44]$$

The assumptions of Equation [44] are so well substantiated by the experiments of many people that within any operating condition of a propeller they may be accepted as true.

Therefore, there must have been an error in the assumptions regarding F_2. These assumptions were:

First, F_2 is always positive. Second, F_2 has a lower limit equal to the total force which would exist on the suction side of the blade were that side acted upon only by vapor pressure. Let this lower limit be called F_0. Third, F_2 remains constant after reaching its lower limit.

Remove the restrictions and consider what might happen in the case of a propeller starting at a low rotary speed N, and then having N increased steadily until the propeller was in an advanced state of cavitation. The lift L would increase steadily with N until F_0 was reached, and then, because we have moved, the first and second restrictions would continue increasing in the same manner until F_2 had considerable negative value, i.e., the water on the back of the blade would be in a state of tension. Suddenly the water columns under tension would rupture, a cavity would form, the tension disappears, only vapor pressure remains, F_2 rises from its negative value to equal F_0, and consequently the lift decreases. Before the rupture and formation of cavities the lift had been

$$L = F_1 - (-F_2) \qquad [45]$$

After the rupture and formation of the cavity the lift becomes

$$L = F_1 - F_0 \qquad [46]$$

and since P_0 is constant for any fixed temperature L begins to increase again with increasing N, but at a lower rate.

For this explanation to be true (*a*) water must be able to transmit tension, and (*b*) it must actually be in a state of tension on the back of a blade shortly before cavitation occurs. It has been shown (16, 17, 18, 19, 20) that one of the definitely established foundations of fact and theory is that water, even when it contains dissolved salts and occluded gases, can transmit a tension of hundreds of pounds per square inch—which is more than ample to cover the case of any known marine propeller. In view of the fact and that this "tension hypothesis" can be used to explain every observed fact in the operation of propellers passing through cavitation, the hypothesis is very enticing.

But the question remains: Is water actually in a state of tension on the back of a blade shortly before cavitation sets in? Several facts make an affirmative answer highly improbable. In every experiment in which water was in a high state of tension the water was either stagnant or moving so very slowly that it must have been a case of pure potential flow. A small flaw, such as a bubble, in the tensile liquid spreads rapidly, almost instantaneously ruptures the liquid column, and relieves the tension. Now it is almost, if not quite, impossible that any propeller was ever operated in a field of pure potential flow, or in a region entirely free from passing bubbles.

However, the experiments of Ackeret (34) practically settle the question. He made a great number of observations on a fixed blade in the variable-pressure water tunnel at Göttingen. His reported observations indicate clearly that the pressure needed to prevent cavitation is proportional to the impact pressure of the undisturbed stream, or to the square of the speed, and that as the impact pressure is decreased by lowering the water speed the pressure needed to prevent cavitation approaches the zero (or the vapor pressure of water). These experiments indicating that there is no appreciable negative pressure, or tension by the water on the blade, taken in conjunction with the remarks in the preceding paragraph are sufficient to warrant the rejection of the "tension hypothesis."

B Formulation of the Problem

The discussion in the latter part of the preceding section makes it obvious that F_2, the total force due to the absolute pressure on the suction side of blade (see Equation [43]) is always positive, and consequently has a lower limit. But the third assumption, that after reaching its lower limit F_2 remains constant, cannot be true, because if it were the zero and negative values of $\partial T/\partial N$ and $\partial Q/\partial N$ found in the T-N and Q-N curves could not exist.

Consider Equation [43], and what happens to L as F_1 and F_2 vary with rotary speed N. Partially differentiating with respect to N gives

$$\frac{\partial L}{\partial N} = \frac{\partial F_1}{\partial N} - \frac{\partial F_2}{\partial N} \qquad [47]$$

We know as a matter of fact, confirmed by the experiments of many men, that $\partial F_1/\partial N$ is always positive. While F_2 always remains positive $\partial F_2/\partial N$ can take negative, zero, and positive values.

The following table shows what happens:

Condition	$\partial F_2/\partial N$	$\partial L/\partial N$
(a)	Negative	Positive and large
(b)	Zero	Positive and smaller
(c)	Positive and $= \partial F_1/\partial N$	Zero
(d)	Positive and $> \partial F_1/\partial N$	Negative
(e)	Positive and $< \partial F_1/\partial N$	Positive and small (between a and b)

Condition (a) represents the normal condition of a propeller operating under noncavitating conditions. Condition (b) represents the condition when F_2 has reached its lower limit, and according to the disproved favorite explanation, makes no further change. Since the forces producing thrust and torque are components of L we know from the T-N and Q-N curves that not only do conditions (a) and (b) occur, but also that (c) and (d) occur. Condition (c) occurs when the thrust and torque reach maximum values; condition (d) occurs when thrust and torque are decreasing with increasing N; condition (c) recurs when thrust and torque reach minimum values; condition (b) recurs as thrust and torque start to rise again; and condition (e) may or may not occur at all (the experimental evidence does not cover sufficient range to establish that).

The circulation, or vortex, theory explains condition (a) since it shows that normally the relative water velocity in the vicinity of the back of the blade is greater than the relative velocity in the undisturbed stream, and that this relative velocity near the back of the blade increases with increasing N. Consequently, the usual condition would be that $\partial F_2/\partial N$ would be negative.

The discussion in section 5A of this paper shows that F_2 has a lower limit, and consequently explains the first occurence of condition (b) when $\partial F_2/\partial N$ becomes zero.

We know by the T-N and Q-N curves that conditions (c) and (d) certainly can occur, that condition (e) possibly may occur, and that condition (b) certainly recurs. Therefore the problem which confronts us is: What physical actions account for these observed occurrences, i.e., what physical actions account for $\partial F_2/\partial N$ becoming positive and later passing through zero?

These odd occurrences happen only when cavitation can be observed to exist. Consequently, it can be asserted that cavitation is the cause. But how can cavitation cause these effects? That is the real problem. Since burbling cavitation and laminar cavitation are so different the answer to this question will be discussed in two separate sections following.

C Retarding Action and Impact Forces of Burbling Cavitation

If $\partial F_2/\partial N$ is ever to become zero or positive, then F_2, after reaching some minimum value must increase.

Many times, while observing the early stages of burbling cavitation with the Edgerton stroboscope, the author has been able to identify some particular bubble among the few then existing and notice that it moved comparatively slowly across the blade. Since the observation of the blade was by flashes of light lasting about five-millionths of a second per revolution, this meant that the bubble clung to the blade for several revolutions. Consequently, the bubble was not moving relatively to the blade with as high a velocity as the undisturbed water.

However, such evidence is not very satisfying as one often has to observe for hours before he can be sure he is identifying any one bubble, and in the advanced stages of burbling cavitation such certainty does not exist. Nevertheless, this evidence was useful for it led to a search of the literature of marine propulsion to discover whether or not anyone had ever made a slow-motion picture of burbling cavitation which would serve as confirmation of these visual observations and carry them on into the case of advanced cavitation.

Mueller (37) made such slow-motion pictures at the rate of 2000 exposures per second and in them the formation, growth, travel, and collapse of individual bubbles can be traced very accurately. When the water velocity in the undisturbed stream was 6.5 meters per second the velocity of the bubbles was 4.5 meters per second. This is definite confirmation of the observation that the velocity of the bubbles is less than the velocity of the undisturbed water, and consequently still less than the velocity which would exist on the back of the blade were there no bubbles. It cannot be stated, or even expected, that the water flowing between the bubbles is as slow as the bubbles. But considering fluid viscosity, it can be stated that a mass of such slow-moving bubbles on or near the back of a blade would exert a retarding action on the water flowing in contact with that blade. When the velocity of a stream of water is retarded, its static pressure rises. Consequently, the retarding action of the bubbles would cause an increase of F_2.

It can easily be observed that many, if not most, of the bubbles collapse before passing the trailing edge of the blade. As a matter of theory, the collapse of a bubble should produce a water hammer and momentarily raise the pressure in the immediately surrounding fluid. As a matter of experimental fact, Föttinger points out that it does (45): "After short intervals of flow, the individual cavities collapsed with hard cracking in parts, which shook the entire tube, and even caused intensive increases in the pressure readings on a spring manometer connected with the nozzle. (Several atmospheres.)"

The experiments of Ackeret (2) are even more definite. Ackeret made direct pressure measurements of the individual impacts due to collapsing bubbles. He used a piezoelectric arrangement. A piston of 2 mm diameter transmits the pressure to the quartz (of the piezoelectric apparatus), increases the electric charge on this, and makes a record on an oscillograph. Each time a bubble collapsed over the piston the pressure rose from 10 to 15 fold.

With pressure increases of such an order it is obvious that when bubbles are collapsing in rapid succession in the area of a burbling cavitation field that the average pressure in that area will exceed considerably the pressure in water at similar velocities but without the collapsing bubbles. This increase in pressure would of necessity raise F_2 above its minimum.

We can now understand how, as the burbling cavitation starts and spreads over the blade, the value of $\partial F_2/\partial N$ changes from its original negative values through zero, to positive—and further that when burbling cavitation had covered the complete back of

the blade it could exert little, if any, additional effect (as the additional bubbles would then be collapsing well astern) and $\partial F_2/\partial N$ would approach zero a second time.

There is no *a priori* reason for asserting that $\partial F_2/\partial N$ would ever equal or exceed $\partial F_1/\partial N$; but from the *a posteriori* reasons that experiments show that in advanced stages of cavitation $\partial L/\partial N$ becomes zero and negative we know that this is true.

Therefore, the theory is stated that: Burbling cavitation reduces thrust and torque because its retarding action on the flow over the back and the impact forces of collapsing bubbles on the back increase the pressure on the back of the blade faster than increased revolutions increase pressure on the face of the blade.

D Laminar Cavitation Increases Total Pressure by Vortex Action

It is a well-known fact that, due to surface tension, the pressure inside a bubble, or cavity, in a fluid is slightly in excess of the pressure immediately outside; but, since this excess pressure varies inversely as the radius of the cavity it may be asserted that the pressure in a laminar cavity cannot be sensibly different from vapor pressure.

Consequently, if the laminar cavity were in contact with the back of a propeller blade, the pressure on that area would equal vapor pressure; and, when the cavity covered the entire back of the blade, F_2 would be at its minimum value and remain constant with further increases of N. In short (see discussion in section 5*B*), $\partial L/\partial N$ could never become zero or negative in the case of laminar cavitation. But the *T-N* and *Q-N* curves show that even in completely laminar cavitation $\partial T/\partial N$ and $\partial Q/\partial N$, and therefore $\partial L/\partial N$ do in fact reach zero and negative values. Since these phenomena could not occur if the laminar cavity were in contact with the back of the blade, it may be asserted that a laminar cavity is not in contact with the back of a blade.

Sections 4F to 4I, inclusive, presented theoretical and experimental evidence to show that a laminar cavity is the center of a vortex, and that the cavity itself is not in contact with the blade but is separated therefrom by the liquid wall of the vortex. The mathematical theories of fluid motion are not yet far enough advanced to calculate with precision the pressure distribution around a vortex as complicated as that originating, for example, at a propeller tip; particularly, with the complication which arises when the central region of the vortex is a vapor-filled bubble so that we are dealing with two fluids (see section 1D).

A mathematical solution has been obtained, however, for the pressure distribution around a rectilinear vortex in a single fluid. A study of this solution will enable us to predict with sufficient qualitative accuracy the effects which the more complicated vortex will have on a propeller when laminar cavitation results. The mathematical solution for the pressure distribution in the neighborhood of a rectilinear vortex in a single fluid is given by Prandtl (39) as

$$p = P_0 - \frac{\rho\Gamma^2}{8\pi^2 r^2} \qquad [48]$$

where p = pressure at any finite point; P_0 = pressure at "infinity;" r = radius of p from center of vortex; Γ = circulation around vortex; and ρ = density of fluid. Thus, the pressure increases radially outward from the center of the vortex, although the rate of increase becomes very small at a short distance from the center.

Qualitatively, at least, this statement must be true for our more complicated vortex surrounding a laminar cavity. Note, however, that since the pressure throughout the cavity must be sensibly equal to vapor pressure, the pressure rise in the liquid vortex must begin with the walls of the cavity. In other words, measurement of r begins at the walls of the cavity and not at the mathematical axis of the cavity.

To understand what happens consider a propeller such as No. 1283-*A* (see sections 2D and 2G) being run at constant revolutions and slip ratio, while the pressure head on the propeller is being varied as when *T-H* and *Q-H* curves in Fig. 12 were obtained. An anchored vortex practically paralleling the leading edge extends from near the root of the blade to the tip and then trails astern. The vortex can be rendered visible as described in section 4H of this paper.

Before cavitation starts the axis of this vortex is merely a mathematical line of low pressure about which the water particles are traveling in more or less helical paths. For a short distance from this line the pressure rises rather rapidly, and thereafter much more slowly until it would hardly affect pressure gradients at a short distance from the axis. Consequently, the vortex would not sensibly affect the region of greatest suction (approximately at the point of tangency, sections 4B, 4C, and 4D).

After cavitation starts the line of low pressure becomes a tube of low pressure, which is the long tubular cavity forming laminar cavitation. The pressure increase starts from the walls of this cavity. Consequently, as the cross-sectional area of the cavity expands (with constant vapor pressure inside) and spreads over the back of the blade, the walls of the cavity carry with them their region of higher pressures and disturb the pressure gradients which otherwise would have permitted regions of low pressure on the back of the blade. The spreading of the relatively higher pressure which surrounds a vortex over a greater area of the back of the blade would increase the total force F_2 on the back and hence decrease the lift L.

Since laminar cavitation spreads with increase of rotary speed N as well as with decrease of pressure in excess of vapor pressure H, we can expect (and actually observe as shown in Fig. 4) effects which follow an increasing N to be similar to those which follow a decreasing H.

Using the same notation as in the preceding sections, as laminar cavitation spreads over the back of the blade, the value of $\partial F_2/\partial N$ changes from its original negative values through zero, to positive and, when laminar cavitation covers the complete back of the blade, it would exert little, if any, additional effect and therefore $\partial F_2/\partial N$ approaches zero a second time.

As in the case of burbling cavitation, there is no *a priori* reason in the case of laminar cavitation for asserting that $\partial F_2/\partial N$ would ever equal or exceed $\partial F_1/\partial N$. However, from the *a posteriori* reasons experiments show that in advanced stages of cavitation $\partial L/\partial N$ becomes zero and negative we know that this is true.

Thus the theory is stated that: Laminar cavitation reduces thrust and torque because the laminar cavity is the center of a vortex surrounded by a region of relatively higher pressure, and as this cavity spreads over, but not in contact with, a blade, it carries this region of relatively higher pressure with it, disturbing the usual pressure gradients, and increasing the total force on that side of the blade.

E Reasons Sufficient to Explain Why Cavitation Reduces Thrust and Torque

In section 2F it was shown that in the case of a given propeller, operating at a constant slip and under a constant pressure, as N increases T and Q increase at first, then decrease, and finally increase again more slowly. Plotting the data gives a double inflection to the *T-N* and *Q-N* curves. These data are experimental facts. They require an explanation.

There have been examined, suggested, and conceivable explanations; and one by one reasons have been found for rejecting them, until the writer developed theories of his own to cover the cases of burbling and of laminar cavitation. These theories explain the

facts by concepts whose perceptual equivalents have been actually disclosed and since "we are to admit no more causes of natural things than such as are both true and sufficient to explain their appearances" it is believed that these theories not only give sufficient reasons to explain why cavitation reduces thrust and torque, but also that they comply fully with Isaac Newton's "Rules of Reasoning" (46) and Pearson's "fundamental canon of the scientific method" (47).

F Reasons Explain the Negligible Effect of Face Cavitation

It has been observed repeatedly that face cavitation, i.e., cavitation on the pressure side of propeller blades, has little or no perceptible effect on propeller performance (48). In view of the marked effect of cavitation on the suction side of the blade, this seems astonishing until we consider the explanations. It was shown that both burbling and laminar cavitation increased the total absolute force on the side of the blade on which they occurred. Therefore, on the pressure side of a blade, as the pressure declined in any area to a degree permitting cavitation, the harmful effect on lift would be more or less offset by the increased forces caused by cavitation. In view of this, and in view of the fact that face cavitation usually occurs in only relatively small areas it is easy to understand why the effects of face cavitation on propeller performance are negligible. Thus the same theories which explain why cavitation on the suction side reduces lift, also explain why cavitation on the pressure side has very little effect on lift.

Acknowledgment

The author is indebted to Dr. Edgar Buckingham, U. S. Bureau of Standards, for the patient and constructive criticism he advanced during many long hours of friendly argument regarding the points in this paper.

Metallurgical Aspects of Hot and Cold Strip for Deep-Drawing Requirements

By J. E. Angle,[1] Gary, Ind., and W. F. McGarrity,[2] Pittsburgh, Pa.

It is the purpose of this paper to give a brief but specific discussion of the basic underlying metallurgical features of hot and cold strip. Recrystallization in hot rolling, effects of finishing temperatures on the grain structure and properties of hot strip, effects of hot and cold coiling, and information regarding forming and drawing qualities of hot strip are discussed. Operating features and limitations are pointed out. Cold-strip processing, together with physical properties and other requirements for deep-drawing work are outlined.

PROBABLY the most important advancement in the sheet industry in this century is the development of the broad-strip rolling process. Compared with the arduous task of making sheets and tin plate by the older hand method, these new mills, with much less effort, can roll steel of considerably higher quality. This method of sheet manufacture has advanced the economical production of the streamlined, all-steel automobile.

By reason of the superior drawing qualities resulting from the process, articles are being made from one piece of steel which formerly were welded or fabricated, and the high finish which can be secured with cold reduction has made it possible to plate steel with nickel or chromium without buffing or polishing. Where half a dozen coats of paint formerly were required on automobiles and furniture, one or two coats are now sufficient.

Many new problems, however, have presented themselves to the strip manufacturer, and particularly to the metallurgist. While there is nothing particularly abstruse or profound about hot- and cold-strip metallurgy in its usual aspects, it may seem somewhat foreign to the steel-mill metallurgist who is engaged in other fields. The purpose of this paper is to give a brief discussion of the basic underlying metallurgical features of hot and cold strip.

At present, deep drawing hot-rolled strip and cold-rolled strip are made almost exclusively from open-hearth rimmed steel ranging from 0.03 to 0.10 per cent carbon, 0.20 to 0.50 per cent manganese, with phosphorus and sulphur as low as possible, and with only a trace of silicon. Good open-hearth practice is of the utmost importance in successfully meeting the exacting ductility requirements that the design of modern deep stampings demands. Cleanliness and freedom from harmful segregation and laminations are vital, as dirt stringers and inclusions in such thin material will often cause fractures during drawing.

The analysis of the steel will vary for different jobs. For large deep stampings, it is usually desirable to ship as soft a sheet as possible to avoid wrinkling in the dies, and, in such cases, the carbon and manganese are held to the lower side of the range. Other stampings are best accomplished with a tough, fine ferritic-grain steel, in which case the carbon and manganese are specified toward the high side of the range. Regardless of use, however, it is always desirable to hold phosphorus and sulphur to a minimum for the sake of ductility.

Recrystallization in Hot Rolling

The microstructure of some of the material produced on a continuous hot-strip mill resembles that pictured in Fig. 1. Especially is this the case when the material is relatively light in gage (0.093 gage) and when it has been finished at a temperature just under the A_3 point. It is not a particularly good structure, and disregarding its possible effect on the subsequent cold-rolled and annealed grain structure, if the material is for cold rolling, it is definitely not as desirable as an even, well homogenized structure.

Such a structure is caused primarily by two factors, which are, segregation, and the amount of reduction the material receives at a certain temperature in the last stand. There are others to be sure, and these have some effect on the finished product, but they do not seem to be as important, and cannot be so well measured, as the two factors previously mentioned.

The method of loading the mills has a great deal to do with this final ferritic grain size, for, with certain reductions on the last stand in a particular temperature range, excessive grain growth will occur. Thus, in hot rolling, a similar critical grain-growth range exists as in cold rolling. This critical growth range is depicted in a three-dimensional diagram in Fig. 2. The peaks in this diagram represent exaggerated grain growth.

While the diagram will be found to have been derived from data on single-stand rollings (4),[3] still, the basic principle has been found to apply also on the continuous-strip mills.

In 1913 and 1916, P. Oberhoffer (1, 2) carried out experiments dealing with the effects of forging at different temperatures on the ferritic grain size. Hanemann and Lucke (3) constructed a quite complete three-dimensional diagram for the effect of forging upon the grain size. However, since it was felt that the grain size, following recrystallization, depended upon the strains in the

Mr. Angle was graduated from Lehigh University in 1932 with the degree of B.S. in metallurgical engineering. After graduation, he was employed by the American Sheet & Tin Plate Company in the metallurgical department of the Gary Sheet Mill, Gary, Indiana. In 1935, he was appointed plant metallurgist, in which capacity he served until the consolidation of the American Sheet & Tin Plate Company with Carnegie-Illinois Steel Corporation.

[2] Strip Metallurgist, Metallurgical Department, Pittsburgh District, Carnegie-Illinois Steel Corporation. Mr. McGarrity, was graduated from Lehigh University in 1931 with the degree of B.S. in chemical engineering. In 1931 he joined the research staff of The Youngstown Sheet & Tube Company as metallographist. During 1933–1934, on a year's leave of absence, he was an exchange scholar from the United States to Germany, at the Bergakademie, Freiberg in Saxony, Germany. Returning to the Youngstown Sheet & Tube Company, he became assistant metallurgist of hot strip. Early in 1936, Mr. McGarrity joined the Carnegie-Illinois Steel Corporation at the McDonald Works as metallurgist of the 43" hot-strip mill; late last year, being transferred to the Pittsburgh Office in his present position.

Contributed by the Iron and Steel Division and presented at the Semi-Annual Meeting of The American Society of Mechanical Engineers, Detroit, Mich., May 17–21, 1937.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

[3] Numbers in parentheses refer to the Bibliography at the end of the paper.

material, and since rolling left strains which were different from forging, Tafel, Hanemann, and Schneider (4) undertook to study the effect of hot rolling on recrystallization. They found the diagram for hot rolling to be different from that obtained for forging. Also, it was concluded that the initial grain size had nothing whatsoever to do with the final grain size. Instead, it was really the reduction in area and temperature of the last pass which determined the final grain size, with the change in structure due to previous passes exerting no influence.

The reduction in the last pass on a hot-strip mill is usually not within the particular critical range herein described as it is more often around 9 to 15 per cent, depending on the condition of the rolls before the last stand, the width of strip, and the gage being rolled. Nevertheless, the surface layers of the strip are often projected into the critical grain-growth range when rolled under A_3 by the amount of cold work on the surface, the spontaneous self-annealing giving rise to the recrystallized coarse surface grain appearing in Fig. 1. Segregation in the center of the strip has prevented grain growth in that region.

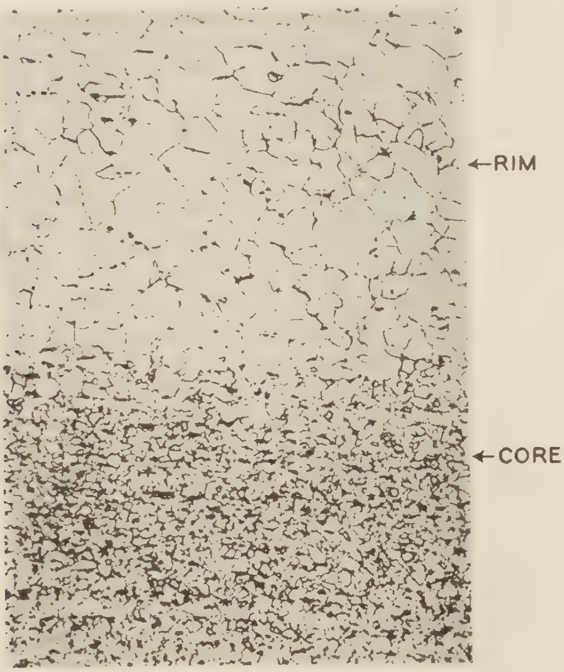

Fig. 1 Typical Structure of Hot Strip Finished Within Critical Rolling Range ×100

In the absence of marked center segregation, and when the reduction and temperature have been such as to be outside of the critical range applying to continuous mills, similar to but not the same as Fig. 2, an equiaxed, medium-sized grain can be obtained (Fig. 4) at temperatures below the A_3 point. It is well known that strip which has been finished above its A_3 point will exhibit small normalized grains, their ultimate size depending upon the temperature and rate of cooling.

In actual practice the microstructure of hot strip varies as follows: If finished above A_3, as the steel enters the last stand, the strip will consist of small normalized grains (Fig. 3). As the finishing temperature drops slightly below this point for a low-carbon steel, the percentage of reduction being suitable, a radical change in structure suddenly becomes apparent. Instead of the small normalized grains, coarse surface grains, or large grains throughout, are found; pebbly Olsen buttons are observed, and the Rockwell value drops to below 48 B. However, it is quite fortunate that beneath this critical range, with a suitable percentage of reduction, is a range where the greatest proportion of strip will consist of quite desirable, soft, medium-sized grains, having hardness values of approximately 50 to 56 B. For deep-drawing hot-rolled sheets, where finishing temperatures above A_3 are not possible, material finished in such a manner has performed quite successfully.

It might be pointed out, however, that strip without such an ideal hot-rolled structure, and with higher hardness values than are considered desirable, often has performed drawing operations which were not considered by many to be possible. Where

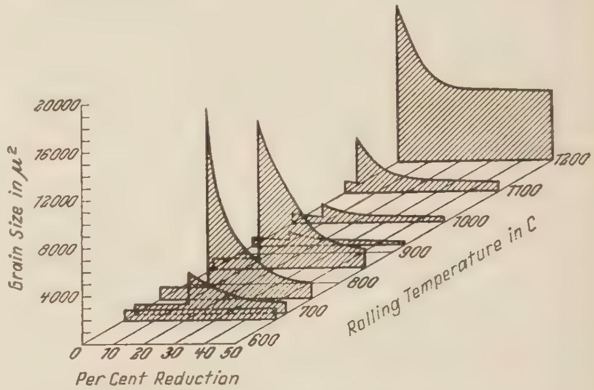

Fig. 2 Recrystallization of Low-Carbon Steel After Hot Rolling (4)

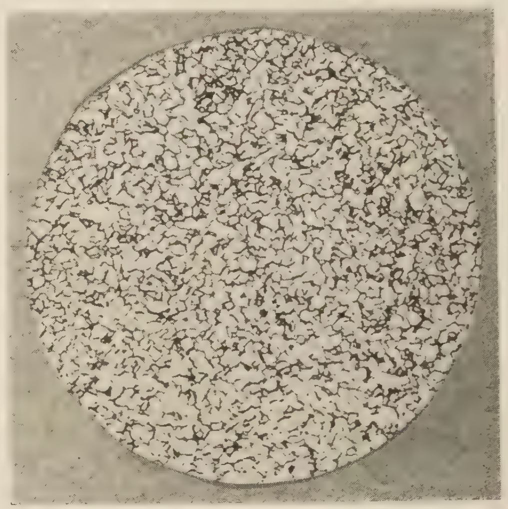

Fig. 3 Typical Structure of Strip Finished Above 1600 F ×100

extra-deep-drawing qualities are required, such strip should be normalized.

When heavier gage material, around 0.135 gage, is finished above the upper critical range, the hardness is appreciably increased over that which would normally be obtained if the strip were finished slightly under this range. Hardening in this case is due both to the refinement of the grains upon passing A_3 and the rapid cooling through the critical range, which affects the form of pearlite. For deep-drawing work, regardless of the slightly higher Rockwell values, this homogeneous material is considered best.

Certain operating limitations make this rather high finishing

temperature difficult to maintain. Chief among them is the formation of a so-called "heat pattern" on the surface of the strip, which, if neglected, will break into rolled-in scale. Appearing at first as a mottled design along one portion of the strip, unless the temperature is dropped, or several rolls in the finishing train are changed, the mottled design spreads across the width of the strip until the whole surface is covered, and later becomes much deeper in effect, resulting in rolled-in scale, with surface pitting. When finishing at higher temperatures, however, besides obtaining more uniform physical properties in the strip, less power is consumed, the strip is easier for the speed operators to handle, and the crown on the rolled material is decreased. Needless to say, too, production can be kept at a high rate.

In the application of the three-dimensional diagram of Fig. 2, it should also be realized that other factors limit the percentage reduction on the finishing stand. With too great a reduction, the proper shape of the strip cannot be attained, the possibility of stretching between the last two stands is increased, and excessive gage variations may result.

Hot and Cold Coiling

Considerable discussion is heard regarding the effect of coiling strip hot and coiling strip cold, especially on wider strip mills. In the authors' experience, the effects of hot coiling are not great, as far as the microstructure is concerned, unless the strip is over approximately 0.083 gage, the coiler quite close to the finishing stands, or the coil extremely heavy. A slight coarsening effect may take place, but the structure is fairly well fixed as it comes out of the last finishing stand, and the cooling is so relatively rapid, both as the strip progresses down the run-out table and while in the coil, that little annealing is possible. The annealing which does take place, however, affects the yield point more than anything else, and tends to coagulate the carbides. Material

Fig. 4 Typical Structure of Strip Finished Below A_3, Outside of Critical Hot-Rolling Range ×100

coiled cold will be found in general to have a proportionally higher elastic ratio than material coiled hot. There is some danger of grain growth in hot-coiled material which possesses a duplex structure (i.e., fine and large grains), although for the light gages, unless coiled very hot, this growth is not considered to be serious.

The use of water on the run-out table to cool the hot strip is excellent practice for strip which will be subsequently cold-rolled and annealed. Quenching tends to assist in the recrystallization of cold-rolled strip, and after annealing, apparently makes for smaller grains with well-dispersed carbides. Quenching by water will tend to show quite angular grains in the microstructure of material finished above A_3. On material finished under A_3, it is considered as a safeguard against possible grain growth in the coil.

Skin Passing, Its Effect on Hardness

For flattening hot-rolled strip, a two-high skin mill is often used in conjunction with roller levelers. With such a mill, only small amounts of reductions are effected per pass. Reductions of more than 0.003 in. are seldom accomplished, the precise reduction varying with the width of strip, the composition, and the grain structure (i.e., ease of deformation) of the metal.

If the material has a fine ferritic grain, it will have a tendency to harden much more than coarse-grain strip with the same amount of reduction. With a reduction of 0.003 in. for a low-carbon, medium-width strip, say 30 in. wide, and 0.130 gage, the hardness increase will be approximately three points, Rockwell B scale. For a lighter gage (e.g., 0.049 in.), and wider strip, the increase in hardness often amounts to six or eight points, providing the structure is fine.

The Heat-Treatment of Hot Strip

As mentioned previously, when extra-deep-drawing qualities are desired from light-gage material which was not finished on the mill in such a way as to obtain a normalized structure, a normalizing treatment must be applied. Likewise, to soften and improve the properties of strip finished above A_3, a normalizing treatment is frequently given the material. When strip, finished off the mill in this latter manner, is normalized, the originally small, even, normalized grains become uniformly larger, the general increase in grain size depending upon the temperature and speed of normalizing and also on the rate of cooling. At the same time and proportionally to these factors, the material becomes softer, the yield point is lowered, and the elongation increases. The tensile strength does not change appreciably, regardless of the speed of normalizing.

When strip or sheets which have been finished on the mill in such a way as to have a duplex structure similar to that of Fig. 1 are normalized, the large surface grains are reduced in size, and the fine interior grains increase in size, so that across the sheet a practically homogeneous ferritic grain size is obtained.

Normalizing, however, unless a suitable furnace atmosphere is maintained, produces a heavy loose scale which is particularly detrimental to die life. Also, where the formed or drawn part is later to be painted or lacquered, a normalized sheet without the scale removed cannot be used for exposed parts. Hence, for these purposes, pickling the normalized sheet or strip is imperative.

For the softening of hard strip where no pickling is allowed, a box anneal is highly desirable. This treatment is carried out at a relatively low temperature, as serious grain growth can be encountered even for short soaking periods, at high temperatures.

Hot Strip to Cold Strip

It has been known for some time that, given sufficient cold reduction, strip can be recrystallized into small or medium-sized equiaxed grains by a box anneal alone. With the older-type two-high cold-reduction mills, the amount of cold reduction was so slight that a normalizing treatment had to be inserted in the process to avoid serious grain growth upon annealing (5). With strip made from four-high tandem cold-reduction mills or other mills which effect heavy reductions in a number of passes normalizing has been done away with almost completely.

The effect of cold reduction is to break up and destroy the hot-rolled grain structure by elongating the grains, Fig. 5. Naturally, a considerable hardening results from the cold-working, and the low-carbon cold-reduced strip usually leaves the mill with a

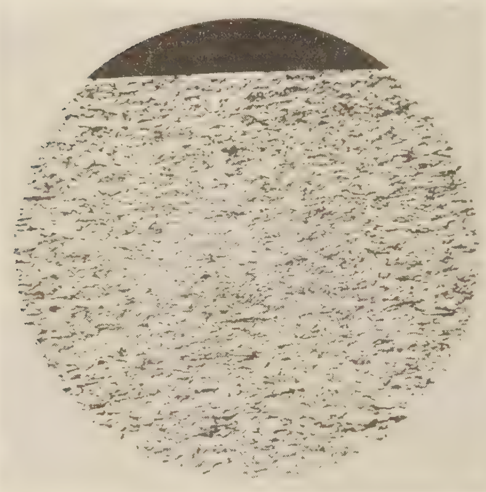

Fig. 5 Typical Cold-Rolled Strip Structure ×100

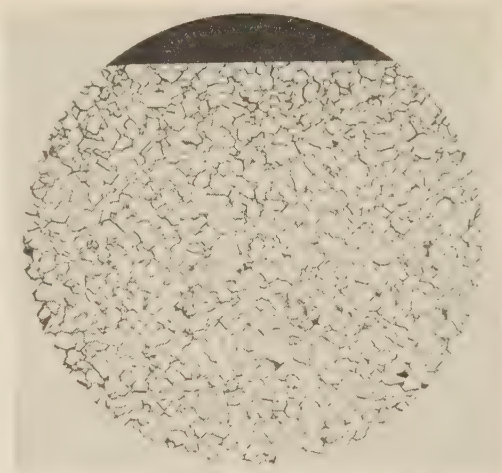

Fig. 6 Typical Cold-Rolled and Box-Annealed Strip for Automobile Sheets ×100

hardness of about 95 Rockwell B. During the cold-working, the rate of hardening is quite rapid at first, then the rate decreases gradually approaching a maximum value. A difference of 10 points Rockwell in the hot-rolled strip may resolve to a difference of as small as one point after sufficient cold reducing.

When reductions totaling some 50 to 65 per cent are effected in these wide four-high mills, with the strip becoming continually harder, pressures of from one to two million pounds per screw are necessary to secure the reductions. Obviously, such pressures place a tremendous strain on the bearings, and these can be one of the most expensive items of cost on either a tandem or reversing mill.

Given this amount of cold reduction, cold-rolled strip can be recrystallized most conveniently by box annealing at temperatures of 1200 to 1380 F. Even at much lower temperatures, recrystallization will take place, but the time required for its completion is excessively long. Box-annealing practices may be divided arbitrarily into two general classifications, either one or the other being used in the cold-strip process, with preference depending upon individual plant supervision. They are: (*a*) box annealing above the A_1 point (1330 to 1380 F approximately), and (*b*) box annealing just below the A_1 point (1200 to 1330 F). Each has its advantages, the former chiefly in the rapidity of the anneal; the latter in the retention of smaller grains and the absence of sticking.

In general, for various deep-drawing applications, the Rockwell hardness of the annealed strip will vary between 40 and 50 B, depending upon the composition of the steel, the grain structure of the hot strip, and the annealing cycle. The A.S.T.M. ferrite grain size will fall between No. 6 and No. 8, and will consist on the whole of quite uniform and equiaxed grains, Fig. 6. The tensile strength will be about 45,000 lb per sq in. yield point about 27,000 lb per sq in., and elongation in the standard 2 in. × 0.500 in. sheet-test specimen of from 35 to 40 per cent with strip 0.0375 in. thick. The character of the yield point is quite interesting. In general, a uniform stress-strain rate will persist to perhaps 28,000 lb, whereupon plastic deformation will begin. Usually, the yield point will then drop as much as a thousand pounds, while considerable elongation occurs. Then, the steel will harden again, and the strength will increase to the breaking point. This elongation at the yield point has been shown to be closely related to stretcher straining (6, 7, 8, 9, 10, 11). It appears that under tension, steel of this sort does not yield uniformly, but that blocks of crystals give way as if they were weaker than their companions. After elongating slightly, not over 10 per cent, there has been sufficient work hardening to increase their strength to that of the rest of the section. The slippage of these blocks of grains shows up on the surface of the steel in lines of depression termed stretcher strains. After more elongation has taken place, they will pull out the remainder of the metal and therefore disappear. In shallow stampings, where the steel is not elongated over 10 per cent these lines will be evident and usually objectionable.

Curiously enough, the slight strain or set imparted to the steel by as little as 1 per cent elongation in temper rolling is usually sufficient to eliminate this tendency, at least temporarily. It is thought that the slight cold working fills the grains of the sheet with slip planes, enabling it to stretch evenly. This is demonstrated quite clearly by the stress-strain diagram of a tensile test. Where before temper rolling there was a pronounced halt at the yield point, there is none after sufficient temper rolling, the curve being smooth to the breaking point.

The other physical tests show little change after 1 per cent temper rolling. Rockwell-hardness values may increase 1 or 2 points, the Olsen cup is generally the same, and the per cent elongation and tensile strength undergo very little change, when tested within a day of temper rolling.

However, what both producers and consumers of cold-rolled strip steel have learned through experience is that an aging process begins immediately after the work hardening produced by temper rolling. The cold working evidently places the steel in an unstable condition, and there is a continual tendency to revert to the original or stable state (12). Unfortunately, the tendency to stretcher strain returns, while the hardness, yield point, and tensile strength increase, with the ductility suffering at the same time. Depending upon the atmospheric temperature at which the steel is held, complete aging may occur in several weeks or in several months. It can be tremendously accelerated by boiling in water or heating in oil at 400 F where it will age in a few minutes.

Where rather large stocks of cold-rolled sheets must necessarily be carried, with some delay between their arrival and use, both the producer and the manufacturer have greatly benefited by the installation of roller levelers at the point where the sheets are to be used, since the effect of aging, as manifested by a return to stretcher straining, is greatly reduced or completely eliminated by this processing.

Cooperative Creep Tests on 0.35 C Steel K20 at 850 F and 7500 Lb per Sq In.

By C. L. CLARK,[1] ANN ARBOR, MICH.

TENTATIVE A.S.T.M. Standards have been prepared by the Joint Research Committee on Effect of Temperature on the Properties of Metals covering both short-time tensile and creep tests at elevated temperatures. Last year a report[2] was submitted by Subcommittee D of Committee 3 setting forth the results obtained by several laboratories from short-time tensile tests at 850 F on a 0.35 per cent carbon steel designated as K20.

The present report, which should be considered as one of progress rather than as a final one, pertains to results obtained from creep tests on this same steel, at 850 F under a stress of 7500 lb per sq in. The procedure recommended in the tentative standard was followed and the steel, which was from the same heat as that used for the short-time tensile tests, is believed to be as uniform as can be obtained on the basis of present knowledge.

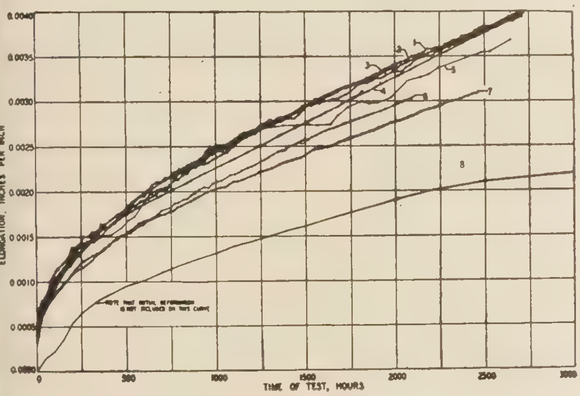

FIG. 1 TIME-ELONGATION CURVES OBTAINED BY EIGHT COOPERATING LABORATORIES, 850 F, 7500 LB PER SQ IN. STRESS

An open invitation was extended to all laboratories to cooperate, and nine requested material for tests. Eight of these nine laboratories have submitted their findings and the ninth has indicated that results will not be forthcoming. The eight cooperating laboratories, arranged alphabetically, are Babcock and Wilcox, Battelle, Bethlehem, Crane, General Electric, Midvale, University of Michigan, and U. S. Steel Research.

The actual time-elongation curves submitted are set forth in Fig. 1. The laboratories are designated with numbers but these do not correspond to the alphabetical listing. It is to be noted that in seven cases the initial deformation obtained upon the application of the load is included while in one case it is not.

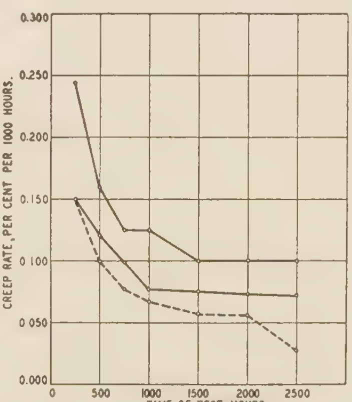

FIG. 2 RANGE OF CREEP-RATE VALUES OBTAINED BY COOPERATING LABORATORIES

From curves of this type both the total plastic deformation and the creep rates at indicated times can be obtained. Table 1 shows the plastic deformations obtained by the various laboratories at the indicated time periods. In order to make the results from all eight laboratories comparable the initial deformation, occurring upon the application of the load, was not considered. The deformations are expressed in per cent and it will be noted that at 250 hr the maximum range is from 0.065 to 0.116 per cent while at 2000 hr, the range is from 0.190 to 0.300 per cent.

[1] Research Engineer, Department of Engineering Research, University of Michigan. Mr. Clark received the degrees of B.S. in chemical engineering in 1925, M.S. in 1926, and Ph.D. in 1928, from the University of Michigan. He has specialized in metallurgy and has served in the department of engineering research at the University of Michigan since 1928.

[2] "Short-Time Tensile Tests at 850 F of the 0.35 Per Cent Carbon Steel Material K20," Trans. A.S.M.E., vol. 58, 1936, paper RR-58-4, pp. 97–101.

Contributed by the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Metals, Subcommittee E of Committee 3, and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Table 2 shows the creep rates obtained by the cooperating laboratories at the designated time periods. The creep rates are expressed in per cent per 1000 hr and are defined as the tangents to the curves at the indicated time periods. The range in these values can best be seen from Fig. 2 which shows the same results graphically. Since the results obtained from laboratory 8 were consistently lower, their values are indicated by a separate line rather than by inclusion in the general range. It will be noted that the range in the creep rates tends to decrease with increasing time and at 2500 hr the total range, for seven of the eight laboratories, is from 0.066 to 0.100 per cent per 1000 hr.

In evaluating these results it cannot of course be assumed that all of the material possessed exactly the same creep resistance. Certain of the available information indicates that not only may variations in the creep resistance exist in different heats of the same analysis but also in different portions of the same heat.

Long-Time Creep Tests of 18 Cr 8 Ni Steel K19 and 0.35 C Steel K20

By HOWARD C. CROSS[1] and J. G. LOWTHER,[2] BATTELLE MEMORIAL INSTITUTE, COLUMBUS, OHIO

This paper, submitted under the sponsorship of the Joint A.S.T.M.-A.S.M.E. Research Committee on Effect of Temperature on the Properties of Metals, is a report on long-time creep tests now in progress on water-quenched 18 per cent Cr, 9.5 per cent Ni, 0.067 per cent C steel K19 at 1200 F and on an annealed 0.35 per cent C steel K20 at 850 F.

One test on the K19 steel loaded to 8345 lb per sq in. at 1200 F was discontinued at 11,467 hours and a second test has now progressed to 15,185 hours.

Of the K20-steel tests at 850 F, one test at 8000 lb per sq in. was discontinued at 10,955 hours, and a second test at 7500 lb per sq in. has now progressed to 12,214 hours.

Introduction

THE STEELS under test have been fully described in previous reports to the Joint Committee and in reports presented to the A.S.M.E.[3,4] and the data herein contained set forth recent results of the continuing tests previously reported to the sponsor societies.[5,6]

[1] Member of research staff, Battelle Memorial Institute. Upon graduation from high school Mr. Cross entered the Metallurgical Division of the Bureau of Standards. While so employed he attended George Washington University, being graduated in 1927 with the degree of B.S. in chemical engineering. In December, 1929, he joined the research staff of the Battelle Memorial Institute. In his work at both the Bureau of Standards and the Institute, Mr. Cross has concentrated on the investigation of the properties of metals at elevated temperatures.

[2] Member of research staff, Battelle Memorial Institute. Mr. Lowther was graduated from the University of Texas in 1928 with the degree of B.S. in mechanical engineering. From 1928 to 1932 he was associated as research assistant in mechanical engineering at the Engineering Experiment Station of the University of Illinois, working on flow of air through orifices. In 1931 he received the degree of M.S. from the University. At the close of that period he was transferred to the applied-mechanics department where his work dealt with fatigue and measurement of stresses in rails. Since September, 1935, he has been connected with the Battelle Memorial Institute on the design and testing of tin-base bearings and on creep of steel at elevated temperatures.

Contributed by the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Steam and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

Creep Tests

18 Cr 8 Ni Steel K19. The time-deformation curves for the 18 Cr 8 Ni steel at 1200 F and 8345 lb per sq in. are shown in Figs. 1 and 2. Table 1 gives a summary of their creep-test data.

At 10,127 hr, the load on specimen B12-4 was removed but the temperature was maintained at 1200 F. The rate of deformation at this time was about 0.000475 per cent per hour and the total deformation was 2.962 per cent.

At the start of the test on specimen B12-4, the deformation resulting from the application of the load was 0.067 per cent. The immediate contraction upon release of the load was about 0.048 per cent, and during the 645 hr at temperature under zero load further contraction to a total of 0.071 per cent took place. At 10,772 hr the load of 8345 lb per sq in. was reapplied and the resultant deformation was 0.045 per cent. After maintaining the load for 695 hr to a total of 11,467 hr, during which time the rate of deformation was about 0.00053 per cent per hr, the load was removed and the immediate contraction was 0.047 per cent.

It may be seen that the contraction resulting from release of the load was of about the same magnitude as the deformation resulting from application of the load. This indicates that the deformation subsequent to that measured upon application of the load is permanent and not recoverable for an 18 Cr 8 Ni steel tested at 1200 F and 8345 lb per sq in.

The test on specimen B12-1 is still in progress at 15,185 hr with a rate of deformation of about 0.00037 per cent per hr and a total deformation of 3.871 per cent. Since the last report at 11,257 hr, the rate has gradually increased from 0.00029 to 0.00037 per cent per hr.

The total deformation of specimen B12-1, nearly 3.9 per cent, is well above that which some designers consider inadmissible for heat-resisting austenitic alloys, even when change of dimensions is not harmful, on the score that brittle failure is impending. The further course of the curve, and whether the specimen continues to stretch or whether it will fail suddenly and in brittle fashion, will be of especial interest.

0.35 C Steel K20. The time-deformation curves for the 0.35 per cent carbon steel at 850 F are shown in Figs. 3 and 4, and Table 2 gives a summary of their creep-test data.

At 9617 hr, the load on specimen 10A-4 (8000 lb per sq in.) was removed but the temperature was maintained at 850 F. The rate of deformation at this time was about 0.000095 per cent per hr and the total deformation was 1.173 per cent.

At the start of the test on specimen 10A-4, the deformation resulting from the application of the load was 0.04 per cent. The immediate contraction upon release of the load was about 0.039 per cent and during the 643 hr at temperature under zero load, further contraction to a total of 0.064 per cent took place. At 10,260 hr the load of 8000 lb per sq in. was reapplied and the resultant deformation was about 0.045 per cent. After maintaining the load for 695 hr to a total of 10,955 hr during which time the rate of deformation was about 0.00011 per cent per hr, the load was removed and the immediate contraction was about 0.043 per cent.

Since this specimen 10A-4 after one per cent total deformation showed a maximum contraction of only about 0.02 per cent more on release of the load than of deformation on application of the

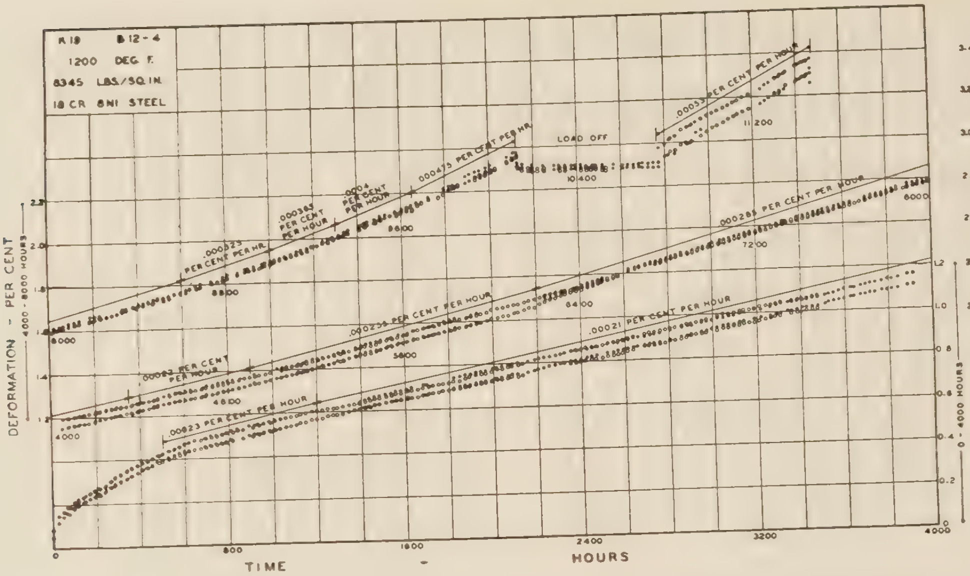

Fig. 1 Time-Deformation Curves at 1200 F for 18 Cr 8 Ni Steel K19, Specimen B12-4

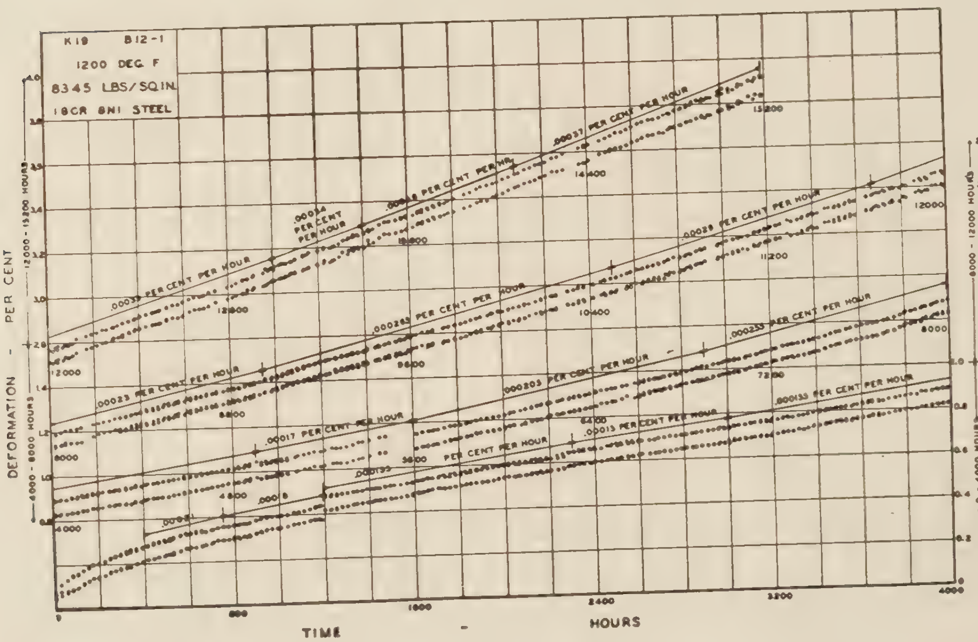

Fig. 2 Time-Deformation Curves at 1200 F for 18 Cr 8 Ni Steel K19, Specimen B12-1

load, practically all of the deformation subsequent to that measured upon application of the load is indicated to be permanent and not recoverable upon unloading.

The test on specimen 25B-5 is still in progress at 12,214 hr with a rate of deformation of about 0.000065 per cent per hr and a total deformation of about 1.045 per cent. The rate has remained practically constant between 0.00006 and 0.000065 per cent per hr since the last report at 8279 hr.

Discussion of the Results of the Creep Tests

For greater ease of comparison the time-deformation curves for the four specimens which were tested are shown as single curves in Fig. 5.

The tests still running have progressed an additional 3825 hr since the last report and continue to indicate that the actual deformations are considerably greater than the values obtained by extrapolation from 2000 hr at the average rate observed between 1000 and 2000 hr for the 18 Cr 8 Ni steel at 1200 F and less than the extrapolated values for the 0.35 per cent carbon steel at 850 F.

For specimen B12-1, the extrapolated value at 15,000 hr would be about 2.43 per cent, whereas the increasing rate since about 3000 hr has caused an actual deformation at 15,000 hr of about 3.81 per cent or about 57 per cent higher than the value estimated by extrapolation.

For specimen B12-4 which has been discontinued at the shorter time of 10,127 hr, the extrapolated value at 10,000 hr would be about 2.42 per cent as compared with the observed actual value of 2.91 per cent, which is about 20 per cent higher. This dif-

[a] At 9617 hr and 1.173 per cent total deformation: immediate contraction upon release of load, 0.039 per cent; greatest contraction during 643 hr at temperature under zero load, 0.064 per cent; immediate deformation upon reapplication of load at 10,260 hr, 0.045 per cent; load on for 695 hr; load off at 10,955 hr; immediate contraction upon release of load, 0.043 per cent; test discontinued.

[b] Test continuing, rate 0.000065 per cent and deformation 1.045 per cent at 12,214 hr.

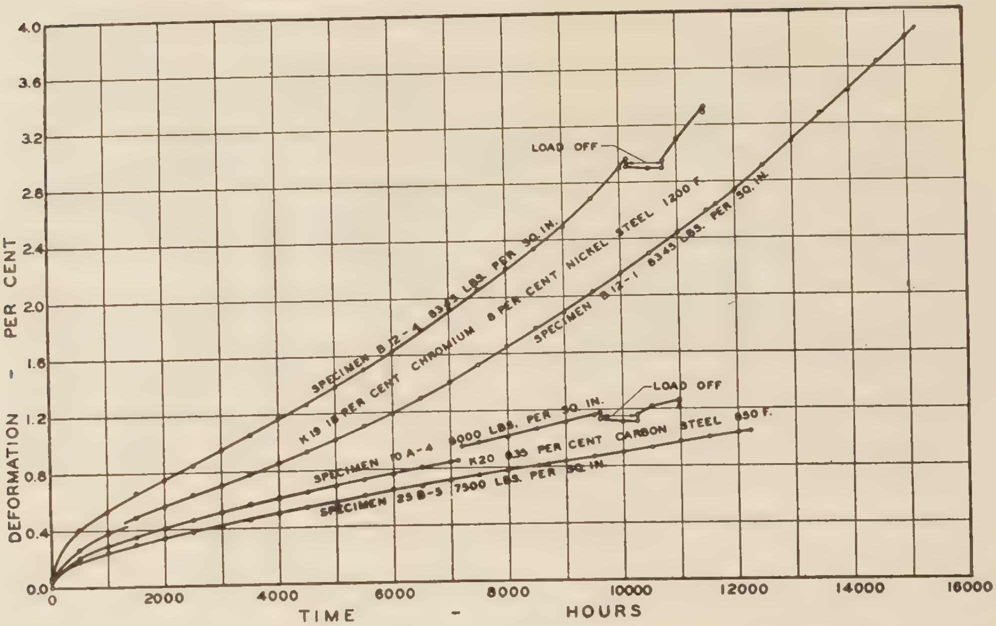

Fig. 5 Time-Deformation Curves for 18 Cr 8 Ni Steel K19 at 1200 F and 0.35 C Steel K20 at 850 F

ference would have increased rapidly if the test period had been further prolonged.

For specimen 25B-5, the extrapolated value at 12,000 hr would be about 1.31 per cent, whereas the decreasing rate since the start of the test has caused an actual deformation of about 1.03 per cent or about 21.5 per cent lower than the value obtained by extrapolation.

For specimen 10A-4, which has been discontinued at the shorter time of 9617 hr, the extrapolated value at 9500 hr would be about 1.30 per cent as compared with the observed actual value of 1.06 per cent, about 18.5 per cent lower than the value obtained by extrapolation.

Hence extrapolation from the 2000-hr test-period data in the case of the 18 Cr 8 Ni steel loaded to 8345 lb per sq in. at 1200 F leads to error which increases in magnitude as the time is increased.

But extrapolation from the 2000-hr test period in the case of the 0.35 per cent carbon steel loaded to 7500 lb per sq in. at 850 F leads to differences on the conservative side.

Since the rate is practically constant only continuation of the test period for this carbon steel will indicate whether the rate will further decrease or ultimately increase and cancel the favorable difference as compared with the extrapolated value.

These data confirm a statement in a previous report that for dependable extrapolations, knowledge of the strain-hardening characteristics of the materials is absolutely necessary.

Note in Fig. 5 the relatively small effect of unloading and reloading of specimens B12-4 and 10A-4.

Examination of Specimens After Creep Test

A, Surface. Figs. 6 and 7 show the external appearance (magnification about 1.75) of specimens B12-4 (18 Cr 8 Ni steel) and 10A-4 (0.35 per cent carbon steel) as removed from the creep-test units with the platinum measuring strips still in place.

Specimen B12-4 (Fig. 6) showed practically no scale and the discoloration was quite even. In this respect it differed from a previous specimen which was removed due to excessive rate of deformation and which showed a spotty appearance. The finger prints shown are the result of handling before the test was started.

Fig. 6 Specimen B12-4 18 Cr 8 Ni Steel, K19 After Removal From Creep Test of 11,467 Hr at 1200 F

Fig. 7 Specimen 10A-4 0.35 C Steel, K20 After Removal From Creep Test of 10,955 Hr at 850 F

Specimen 10A-4 (Fig. 7) showed a characteristic reddish iron-oxide scale which was cracking and splitting but there was evidence that it had been quite adherent until the deformation had caused the scale to part.

B, Structure. Fig. 8 shows the structure of a longitudinal

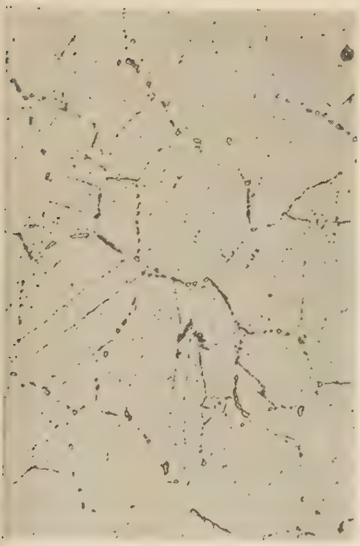

Fig. 8 Specimen B12-4 18 Cr 8 Ni Steel K19 After 11,467 Hr at 1200 F. Specimen Etched With Aqua Regia in Glycerin ×500

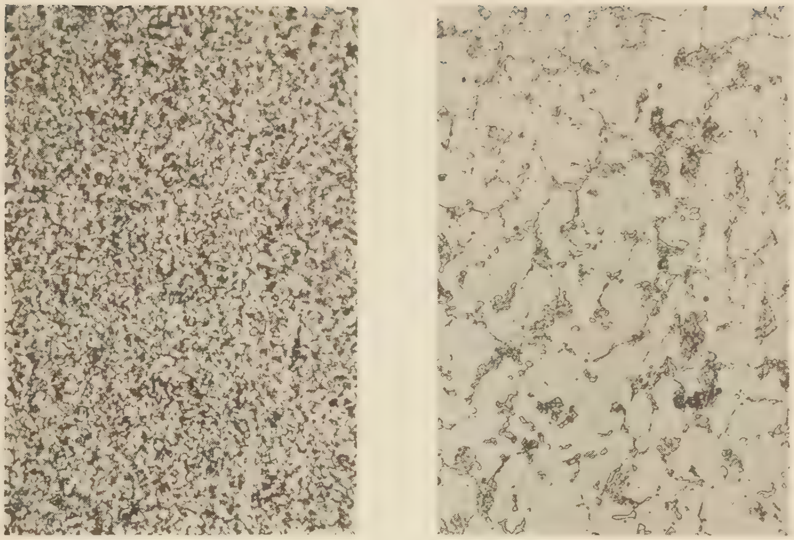

Fig. 9 Specimen 10 A-4, 0.35 C Steel K20 After 10,955 Hr at 850 F. Specimen Etched With 2 Per Cent Nital
(Left: Specimen ×100; right: Specimen ×500.)

section taken from the center of the creep-test specimen B12-4 (18 Cr 8 Ni steel) after test of 11,467 hr at 1200 F. Carbide precipitation has taken place in the grain boundaries, along twinning planes, and also within the grains themselves. Agglomeration of the carbide particles is also apparent. Careful examination of the specimen showed no difference in structure between the center and surface. No decarburization or intergranular parting or oxidation was evident.

Fig. 9 shows the structure of creep-test specimen 10A-4 (0.35 per cent carbon steel) after test of 10,955 hr at 850 F. Little change has taken place in this specimen. Possibly when compared with the structure as heat-treated the carbides are more spheroidized and agglomerated. There seemed to be no difference between the center and surface. Below the scale at the surface no decarburization was evident.

C, Impact Resistance. Two round Izod impact-test specimens (V notch) were machined from the reduced sections of creep-test specimens B12-4 and 10A-4.

The results obtained from the impact tests were as follows:

	Izod impact resistance, ft-lb As heat-treated	
18 Cr 8 Ni steel K19.......	101–107	B12-4 (11,467 hr at 1200 F) 50–58
0.35 per cent carbon steel K20....................	48–55	10A-4 (10,955 hr at 850 F) 54–55

While the impact resistance of the 18 Cr 8 Ni steel specimen B12-1 has dropped considerably from the value as heat-treated, a final Izod impact resistance of 50–58 ft-lb is usually taken as indicating ample toughness for any practical purpose.

Since the metallographic examination of the 0.35 per cent carbon-steel specimen 10A-4 showed but little change in structure during the creep test the lack of change in impact resistance is consistent with the structure.

Conclusions

The long-time creep tests on the 18 Cr 8 Ni steel at 8345 lb per sq in. at 1200 F show increasing rates of creep, thereby increasing the difference between the actual deformations measured and the value obtained by extrapolation from the 2000-hr test period.

The long-time creep tests on the 0.35 per cent carbon steel at 8000 and 7500 lb per sq in. continue to indicate extrapolation from the 2000-hr period conservative as compared with the actual deformation measured. It is obvious that without knowledge of the strain-hardening characteristics of a given steel, quantitative extrapolation from a single creep test, even of 2000-hr duration, is unlikely to be accurate. A family of creep curves from which may be deduced the loads and temperatures at which the curves change from the type that ultimately shows an increased rate of flow to that which ultimately shows a decrease, or some other method of determining the ultimate strain-hardening properties for different loads and temperatures, is necessary for complete evaluation.

Experiments on both steels on unloading, holding at temperature with zero load, reloading, and again unloading, indicate that practically all of the deformation subsequent to that measured upon application of the load at the start of the test is permanent and not recoverable.

Examination of an 18 Cr 8 Ni steel specimen after creep test shows carbide precipitation and agglomeration but impact tests, although indicating a reduction from the impact resistance as heat-treated, still indicate a satisfactory toughness.

Examination of a 0.35 per cent carbon-steel specimen after creep test showed little change in either structure or impact resistance from the heat-treated condition.

Constant Strain-Rate Tests on 0.35 C Steel K20 at 850 F

By A. NÁDAI[1] and E. A. DAVIS,[2] EAST PITTSBURGH, PA.

Introduction

IN CONTINUATION of the program of accelerated tests on the effect of the speed of deformation upon the yield stress of metals at elevated temperatures, constant strain-rate tests were made in tension on a 0.35 per cent carbon steel at 850 F. This is part of a testing program carried out at the Westinghouse Research Laboratories for several years on the creep and plastic flow of metals. The constant strain-rate tests to be reported briefly here were made for various reasons. One was to extend the range of speeds of deformation over a much wider scope than is usually found in the standard long-time tensile creep tests made at elevated temperatures. In the ordinary creep test, the load is kept constant and the range of speeds of deformation is confined to comparatively small velocities of stretching, so that tests must run for a long time. The usual time is three months with creep rates of the order of 10^{-8} in. per in. per hr or approximately 0.01 per cent deformation per year. In the constant strain-rate tests, strain rates about a thousand million times larger can be applied or of the order of 10 in. per in. per hour. A second reason for making such tests is that they can be carried out in a comparatively simple manner, and when properly analyzed may furnish information which can be utilized to predict the behavior of metals in the range of the slow rates of flow found in the ordinary creep tests made under constant stress. A third and important reason for making tensile tests under controlled rapid strain rates is that a few tests of this short duration together with one or two long-time tests reduces the time required for a determination of the relation of stress to velocity of deformation (the creep laws). It is realized that certain conditions cannot be reproduced by shortening the time of testing from several months to a few hours or days. It must, however, be said that the effect of prolonged exposure of a metal to high temperature, upon the mechanical properties could be determined by making short mechanical tests from time to time during the heating process. In other words, samples of a metal which have been kept at elevated temperature over the required long periods of time when subsequently tested in rapid tests, show the principal effects.

[1] Research Laboratories, Westinghouse Elec. & Mfg. Co. Mem. A.S.M.E. Dr. Nádai was formerly professor of applied mechanics of the University of Göttingen in Germany, and since March, 1929, he has been connected with the research laboratories of the Westinghouse Company and with the graduate school of the University of Pittsburgh.

[2] Research Laboratories, Westinghouse Electric & Manufacturing Co. Mr. Davis was graduated from the University of Pittsburgh in 1932 with the degree of B.S. in mechanical engineering. He entered the employ of the Westinghouse Company in 1933 and in April, 1934, was transferred to the research laboratories.

Contributed by the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Metals, Subcommittee E of Committee 3, and presented at the Annual Meeting of The American Society of Mechanical Engineers, held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

It is probable that the changes in the internal structure of metals due to a long exposure to high temperatures under unfavorable conditions, such as the presence of corroding atmospheres, could be tested in this way.

In order to compare strain rates obtained from rapid tensile tests with those observed in ordinary long-time creep tests, N. L. Mochel, secretary of the A.S.T.M.-A.S.M.E. Joint Research Committee on Effect of Temperature on the Properties of Metals secured a lot of 0.35 per cent carbon steel from the Bethlehem Steel Company and made a portion of this steel available for the controlled strain-rate tests. According to the intention of the Joint Committee several cooperators were asked to run comparative long-time tensile creep tests of 1000 hr and also of a much longer duration.[3]

There was, therefore, offered a unique opportunity to correlate the entirely different method of rapid tests in which the speed was kept constant with the observations made at several laboratories where tests were run under constant stress.

Material

The material used was a 0.35 per cent carbon steel, which was received fully annealed.[4] A one-inch diameter bar of this material, marked 12 and 12B, was received from N. L. Mochel of the Westinghouse South Philadelphia Works. This bar, which was about seven feet long, was slightly bent at the middle but enough material was obtained from the straight ends to make five tensile-test specimens.

Testing Equipment—Test Pieces

These tests were run on the constant strain-rate apparatus built into a modified ten-ton Amsler testing machine.[5] The hydraulic drive of this machine was used only as a load indicator, and the testing bars were stretched at constant relative speeds of the heads by means of a screw mechanism, electrically driven by means of interchangeable-gear speed reducers. The speed range extended from one to 20,000 and from one to 10^8 when the long-time tests of Battelle were included in the comparison.

The shape of the test pieces is shown in Fig. 1. They had a four-inch gage length. The heating furnace had an overall length of twenty inches and was provided with a narrow window, five inches long through which the elongation was optically measured with two micrometer telescopes. The gage marks were made by spot welding small platimum ribbons on the side of the bar. The measurements were made by focusing two telescopes on the edges of these ribbons.

[3] Compare: Report of Joint Research Committee on the Effect of Temperature on the Properties of Metals, preprint No. 25, 1936, A.S.T.M., p. 17, Appendix II, containing the newest data on two long-time tests on 0.35 per cent carbon steel at 850 F of 9620 hr at 8000 lb per sq in. and of 8690 hr at 7500 lb per sq in., respectively. Creep curves are shown in Figs. 4 and 5 of this report submitted by H. C. Cross and F. B. Dahle, Battelle Institute, Columbus, Ohio.

[4] A full description of the material and its preparation is given in the Progress Report by Subgroup D on Short-Time Tensile Tests to the A.S.T.M.-A.S.M.E. Joint Research Committee on the Effect of Temperature on the Properties of Metals, Trans. A.S.M.E., 1936, vol. 58, page 97, RP-58-4.

[5] A description of the apparatus will be found in a paper soon to be published on constant strain-rate tests with stainless steel.

Four thermocouples were clamped on each test piece before it was put in the furnace. Two of these were on the gage length and one was on each shoulder. The temperature was adjusted until the four thermocouples agreed within one deg C. After the test was in progress, the temperature could be read only on the shoulders because the clamps at the gage-length positions became loose. The temperature was kept to within 2 deg of 850 F during the tests and throughout the comparatively short gage length of the test bars.

Test Results

Stress-strain curves, for various velocities, for these tests are plotted as shown in Fig. 2. Fig. 3 shows the first portion of them corrected for reduction of area. It can be seen that the yield stress changes quite considerably for a given change in speed; that is, the material is already quite sensitive to speed changes at 850 F. This steel was not very strong and started to deform plastically at rather low stresses, but was exceptionally suitable for an investigation of the effect of the speed of deformation at this temperature. It can be noticed that the material is

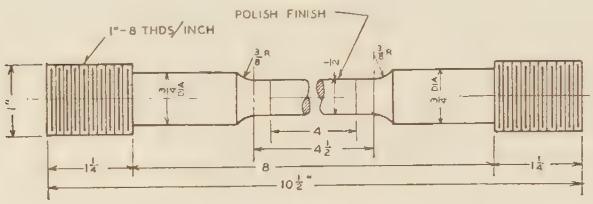

Fig. 1 Tension Test Piece

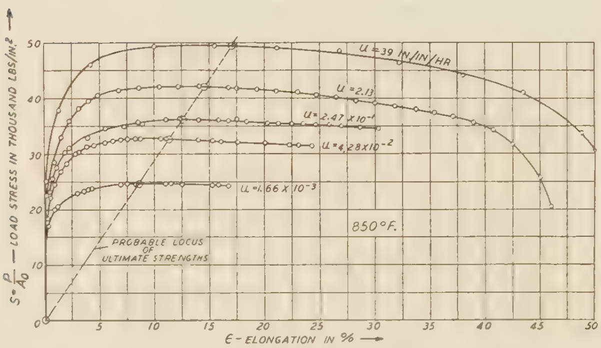

Fig. 2 Stress-Strain Diagrams for 0.35 C Steel K20 Taken at Constant Strain Rates. $u = d\epsilon/dt$ = Constant

still in the strain-hardening range. The ultimate strength was not attained until the strain reached about ten per cent, while in some previous tests on a twelve per cent chromium steel, the ultimate strength occurred at about three per cent strain at the same temperature.

Fig. 4 shows how the yield stress σ changes with the plastic-strain rate $u'' = d\epsilon''/dt$, ϵ'' = plastic strain. The points to the right of $u'' = 10^{-3}$ represent the tests made in this investigation at the Westinghouse research laboratories. Each line represents the relation between stress and speed of deformation for a given amount of plastic deformation. The four points to the left represent the tests made on this same material at the Battelle Memorial Institute and reported by Cross and Dahle. These four points were obtained by reading the speed of deformation at one-half per cent strain from Figs. 6, 7, and 8 of the Cross and Dahle paper.[6]

[6] "Long-Time Creep Tests of 18 Cr 8 Ni Steel and 0.35 Per Cent Carbon Steel," by H. C. Cross and F. B. Dahle, Trans. A.S.M.E., vol. 58, 1936, paper RP-58-3, p. 91.

Discussion of Test Results

Since these tests are designated as constant-rate tests, it might be well to consider what is meant by such a test. In dealing with large deformations or with creep phenomena, there are three

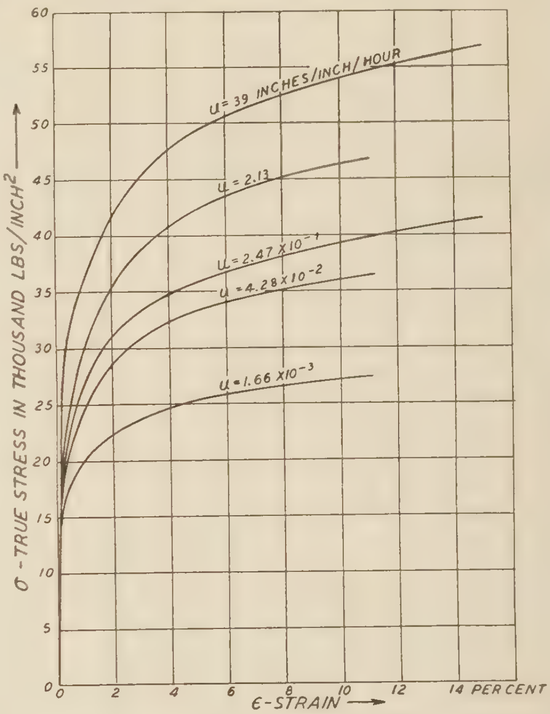

Fig. 3 Stress-Strain Curves for 0.35 C Steel K20 at $u = d\epsilon/dt$ = Constant, 850 F

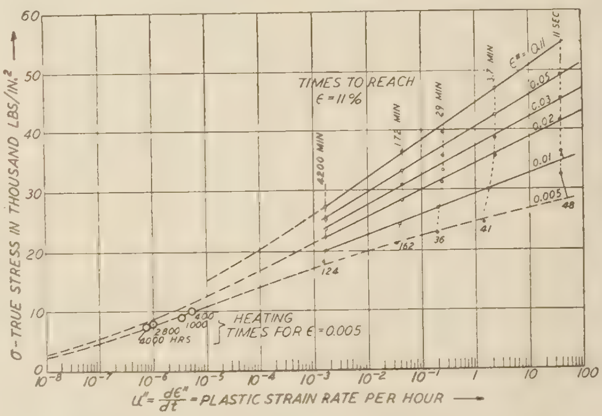

Fig. 4 Stress-Strain Rate Curves for 0.35 C Steel K20 at 850 F

strains that must be considered; the total ϵ, the elastic ϵ', and the plastic ϵ'', which are related by the expression

$$\epsilon = \epsilon' + \epsilon'' = \frac{\sigma}{E} + \epsilon''$$

There are also three corresponding strain rates given by u, u', u'' or

$$u = \frac{\partial \epsilon}{\partial t} = \frac{\partial \epsilon'}{\partial t} + \frac{\partial \epsilon''}{\partial t} = \frac{1}{E}\frac{\partial \sigma}{\partial t} + u''$$

The ideal constant rate test would be one in which the plastic strain rate, u'' was kept constant, but in actual testing with the equipment available, the best that can be hoped for is to keep the total strain rate u constant. It was found when this was tried that the rate u did not approach a constant value until the bar was stretched plastically about one-half per cent. This lag is due to the elasticity of the parts of the testing machine and probably to some looseness in the grips and heads. It is only toward the latter part of the test, where the load is increasing slowly, that a constant plastic-strain-rate test is realized. In Fig. 4, a constant plastic-strain rate would be represented by a vertical line through the curves. In the actual test u was constant, not u'', therefore, the vertical dotted lines joining the points of any one test tend to curve to the left at small strains, thus indicating lower plastic-strain rates for the first part of the tests.

In Fig. 4, the points representing a given amount of plastic strain, ϵ'' = constant are very close to a straight line. This would mean that the value of σ_0 in the logarithmetic speed equation, $\sigma = \sigma_0\left(1 + ln\frac{u''}{u_0}\right)$, is a constant over the range of speeds used in these tests. At lower strain rates, u'', these lines cannot remain straight and must show their convex side toward the abscissa axis. From similar tests made with stainless steel at 850 F, it was evident that they become flatter at still larger strain rates than those indicated in Fig. 4. This seems to be the general behavior for nonaging metals. In Fig. 4 the line for $\epsilon'' = 1/2$ per cent, is slightly curved. This departure from the straight line could be due to aging of the metal, for even though the strains are the same, the times required to reach these strains are very different. In order to check whether aging had an effect, a block of the 0.35 carbon steel was kept at 850 F without stress for seven months. The hardness was measured periodically on a Vickers hardness machine, but the change was within the accuracy of the machine, so that practically no change in hardness or aging was noticed in that time.

One thing of importance that might be noted is the fact that if any one of the points for the creep tests be connected by a continuous curve (here it was approximately a straight line) with a point for one of the rapid tests, the stress-strain rate relationship would be given almost as accurately as it could be determined from the four long-time creep tests. For obtaining design data for a material, it would not require the need of as much long-time test equipment as heretofore used, because one single long-time test would perhaps permit one to locate the curve with the required accuracy. It seems from these tests, that the curve could be drawn with a sufficient degree of accuracy without having even one long-time test available, using only the points obtained at the rapid strain rates. It is noted that the shortest test had a duration of less than one minute, while the longest constant strain-rate test lasted four to five days.

Along the lowest curve corresponding to a plastic strain of $1/2$ per cent in Fig. 4, the *heating times* are inscribed in hours which elapsed from the beginning of a test until an elongation of $1/2$ per cent was reached. It is quite interesting to note that the point at $u'' = 10^{-6}$ with a heating time of 4000 hr (one-half year) taken from the report of Battelle Institute, fits perfectly well with the curve in which some of the points correspond to the short heating times of one and one-half days. Along the upper curve for ϵ'' = 11 per cent in Fig. 4, the testing times are shown (in minutes) to reach 11 per cent strain. They varied between 11 sec and 4200 min.

It must be noted, that when age hardening becomes pronounced in a metal, the extrapolation of the curves shown in Fig. 4 and defined by the rapid tests, into the region of the slow creep tests where the time of exposure to temperature increased quite considerably, needs further careful considerations.

Some information with regard to the numerical value of the important constant σ_0 appearing in the logarithmetical stress versus speed-of-strain formula covering the straight portion of the curves of Fig. 4 is of interest.

$$\sigma = \sigma_0 (1 + ln \left(\frac{u''}{u_0}\right)$$

(σ = yield stress, $u'' = d\epsilon''/dt$ = the plastic-strain rate, u_0, σ_0 = constants) σ_0 can be computed from the slopes of the straight portion of the inclined lines in Fig. 4. The values of the constant σ_0 for various amounts of strain hardening expressed through the plastic strains ϵ'' (such as for example $\epsilon'' = 1/2$, 1, 2, 3, 5, and 11 per cent) are plotted in Fig. 5. It must again be noted, that the value of the constant σ_0 depends upon the previous history of the material, as was observed in numerous creep tests made with copper.

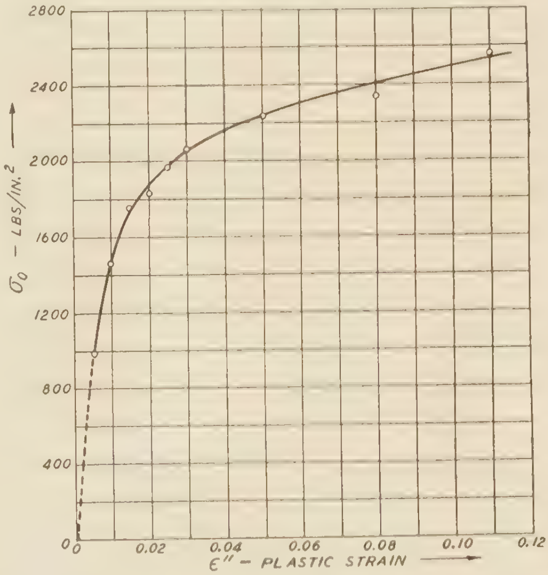

Fig. 5 Curve Showing Relations Between σ_0 and Plastic Strain for 0.35 C Steel at 850 F

Another interesting conclusion can be drawn from Fig. 2. It can be seen from this figure that the ultimate strength S_m decreases as the rate of strain u diminishes and at the same time the strain ϵ_m decreases, at which the maximum of the load S_m occurs. In Fig. 2, a dotted line has been drawn showing the probable locus of the points (ϵ_m, S_m). This curve seems to pass through the origin and is nearly a straight line having the equation

$$\epsilon_m = 3.5 \times 10^{-6}/S_m$$

Along this line are found the values of the strain ϵ_m at which the load maxima S_m occur at the various constant strain rates and at which the equilibrium in a tensile test made under these conditions becomes unstable.

Conclusion

When yield stress σ is plotted at a given strain ϵ'' against the logarithms of the speeds of stretching u'' within the range of speeds which were here considered the curves $\sigma = f(u'')$ for the 0.35 carbon steel approximate straight lines thus indicating that for the 0.35 carbon steel at 850 F

$$\sigma = \sigma_0\left(1 + ln\frac{u''}{u_0}\right)$$

For much smaller velocities these lines must approach asymptotically the value $\sigma = 0$.

When the speed of stretching was increased in the ratio of approximately 20,000 to 1 the yield stress was doubled. Fig. 2. The 0.35 carbon steel at 850 F was therefore exhibiting a very pronounced effect of the speed of deformation. Results obtained in these controlled, rapid strain-rate tests (of a duration of a few minutes, several hours, or a few days) checked well with results obtained in long-time creep tests made at Battelle Institute over periods of over 8000 hr duration.

A Relaxation Test on 0.35 C Steel K20

By ERNEST L. ROBINSON,[1] SCHENECTADY, N. Y.

IN CONNECTION with the cooperative program of high-temperature creep tests on 0.35 per cent carbon steel sponsored by the Joint Committee, the General Electric Company has run what it usually calls a "flow-rate test" and the results are presented herewith for their comparative value.

In conducting this type of test a relatively high initial stress is applied which corresponds to the initial tightening of a bolt, care being taken not to exceed a specified total extension. Initial creep is rapid and the applied load is reduced each time the total extension reaches the specified limit. The immediate reduction in elastic extension with each reduction of load permits further creep within the limit, and this creep takes place more and more slowly due both to the reduction of load and to the strengthening up of the material under whatever properties of initial strain hardening it may possess.

The test is a close approximation to what happens in a bolt in an unyielding flange. It might properly be called a test at constant extension as distinguished from the ordinary test at constant stress.

The 0.35 carbon steel, designated as K20 was manufactured by the Bethlehem Steel Company and distributed by the Joint Committee to cooperating laboratories. It has been fully described in the published reports sponsored by the Committee.

Fig. 1 shows the test results for 3670 hr at 850 F on the four specimens cut from bar 14 of this material. Specimen 14A1 was tested at 7500 lb per sq in. constant stress; 14A2 at 5500 lb per sq in. constant stress; 14A4 at 4000 lb per sq in. constant stress; and specimen 14A5 at 1.5 mils per in. constant extension.

Fig. 2 is the well-known log-log plot of stress vs. rate of creep. In this diagram line 1 represents the relaxation, or flow-rate test at constant extension, on bar 14A5. Line 2 represents the results of the several constant-stress tests at the end of 500 hr, and line 3 represents the same curves at the end of 3500 hr.

The differing slopes obtained in the two types of test are, of course, to be expected, since quite different conditions are represented. This brief statement is not intended to deal with the interpretation of the constant-stress results.

The fact that line 1 in Fig. 2 is straight over a long range of stresses leads to a simple mathematical representation of the results. It may also be said that this test is typical of hundreds of similar tests run by the General Electric Company on many materials and it is not an isolated case.

If X represents the total creep, S the residual stress at time t, E the modulus of elasticity, S_0 the nominal creep strength for a rate r_0 and n is the slope of line 1, the equation of the line is

$$r = (r_0/S_0^n)S^n = dX/dt$$

The condition of constant extension prescribed for the test is

$$X + (S/E) = S_1/E$$

in which S_1/E is the prescribed total extension and S_1 would be the initial stress in the bolt if it could be tightened instantly without any plastic extension during the application of the stress.

The two relations stated lead directly to the following expression between elapsed time, the nominal physical properties determined by the relaxation test, and the initial and residual stresses

$$t = \frac{S_0^n}{(n-1)\, r_0 E^n}\left[\left(\frac{E}{S}\right)^{n-1} - \left(\frac{E}{S_1}\right)^{n-1}\right]$$

Examination of this formula shows that it represents the difference of two time quantities. Ordinarily, and whenever the initial stress is relatively high, the second term will be found to be a very limited number of hours. If a stress-time curve is plotted, it will be found that after a few weeks or months a knee has been passed and further relaxation is very gradual, the few hours represented by the second term of the formula being of little significance.

Hence for year-long computations the formula may be written

$$t = \frac{S_0^n}{(n-1)\, r_0\, E\, S^{n-1}} \quad \text{or} \quad S = \sqrt[n-1]{\frac{S_0^n}{(n-1)\, r_0\, E\, t}}$$

It is interesting to note that the complete expression may be written in terms of extension by redefining X as the residual elastic extension and letting X_0 represent the elastic extension corresponding to the nominal creep strength S_0 and X_1 the specified limiting extension for the test thus

$$t = \frac{X_0^n}{(n-1)\, r_0}\left[\frac{1}{X^{n-1}} - \frac{1}{X_1^{n-1}}\right]$$

These expressions connecting time with stress or extension may be plotted to yield residual stress or total plastic extension, Fig. 3.

There are many reasons why relaxation tests at constant extension are useful and significant. Perhaps the least fundamental but a noteworthy reason is that behavior under a number of stresses is obtained from a single bar, while a battery of tests is required to give comprehensive information under a series of constant stresses. The step-down test is thus economical of furnace space.

The period of initial rapid creep is usually over in a few weeks and the knee of the relaxation curve passed, so that test results based on two or three months may be extended with confidence to a year or 10,000 hours. It is usually reasonable to suppose bolts may be retightened that often. In comparison with this, constant-stress tests may or may not give, in the same time period, results that can be extrapolated, depending on the stability of the material. However, it does not appear likely that relaxation tests can replace constant-stress tests. Both are necessary even if the latter do require longer time periods.

As a means of comparing the metallurgical behavior of materials under conditions approaching actual service the step-down test is good for several reasons. In the first place, the

[1] Turbine Engineering Department, General Electric Co. Mem. A.S.M.E. Mr. Robinson was graduated from the St. Lawrence University in 1911 and from the Harvard Graduate School of Applied Science in 1914 (M.C.E.). For three years he was engaged in construction work and the design of steel and reinforced-concrete structures in New York and in water-power engineering in New England. During the war he served in the Oise-Aisne offensive as First Lieutenant with the 302nd Engineers, U. S. A., and later as Captain and Adjutant of the 2nd Engineer Training Regiment. For the last 18 years he has been employed in his present capacity.

Contributed by the A.S.T.M.-A.S.M.E. Joint Research Committee on the Effect of Temperature on the Properties of Metals and presented at the Annual Meeting of The American Society of Mechanical Engineers held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

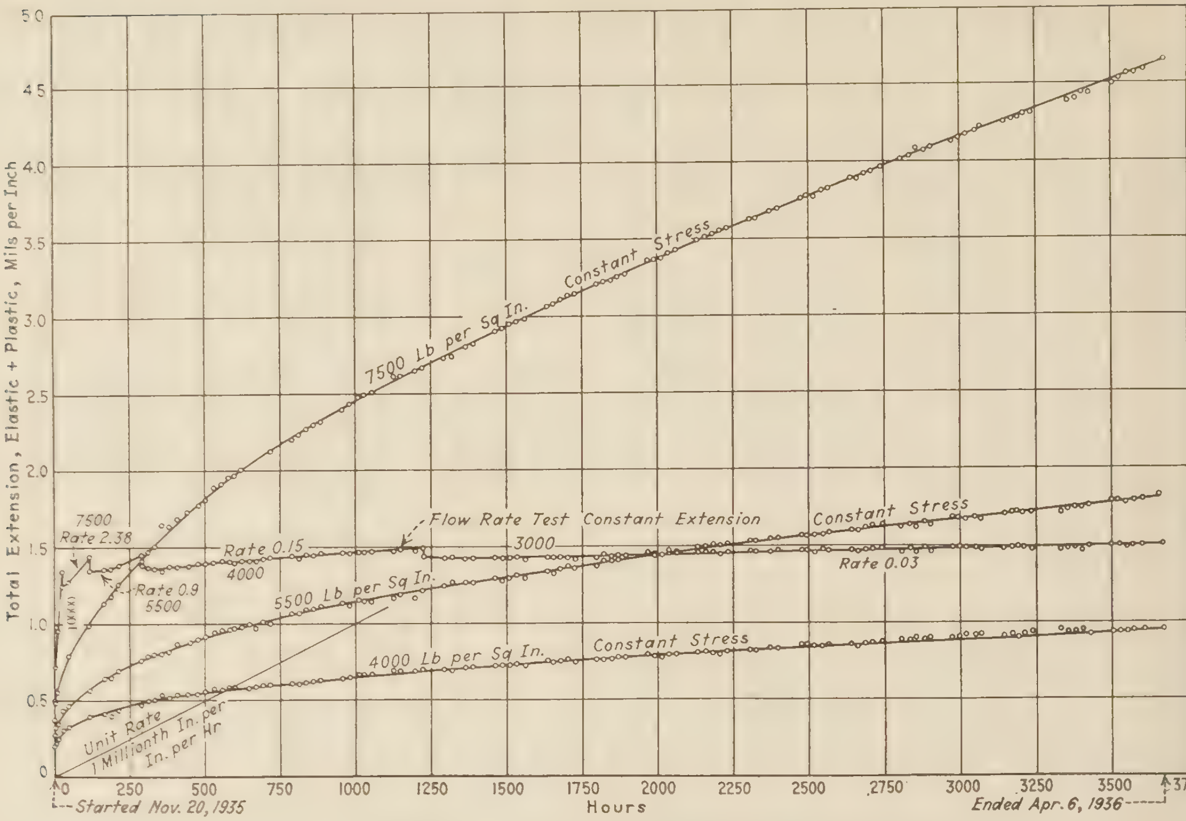

Fig. 1 Test Results on Four Specimens of 0.35 C Steel K20 at 850 F

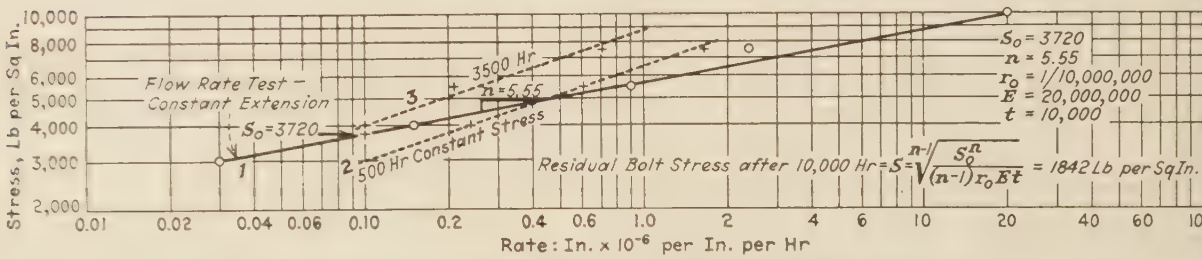

Fig. 2 Log-Log Plot of Stress Vs Rate of Creep on 0.35 C Steel K20 at 850 F

amount of stress relief is a direct measure of the initial creep effects. A material with a high rate of initial creep relaxes quickly and the residual stress is low. On the other hand, if the residual stress is high so that a bolt would stay tight, the test indicates that initial creep effects are small, the material getting its grip with a minimum of internal readjustment.

Furthermore, at the conclusion of the test the relation between the final stress and the corresponding rate of creep gives a good index of the long-time behavior of the material. The nominal creep strength corresponding to a specified rate describes that quality of the material while the residual stress after a specified time also includes initial effects.

Another real virtue of the relaxation test is that it definitely safeguards the test from any excessive strain-hardening effects. With constant-stress tests, if too big a stress is applied to a bar it will stretch beyond reason and the test will be largely wasted. Such a result is impossible with the step-down method, the strain-hardening effect being strictly limited by the method itself to values applicable to service.

Also the test gives information directly applicable to bolts in

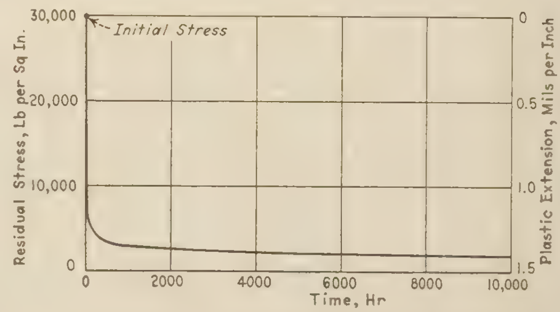

Fig. 3 Computed Bolt Performance, 0.35 C Steel K20 at 850 F

service or machine parts assembled with a shrinkage allowance.

It should be noted that when one half of such an assemby (the flange through which the bolt passes, for instance) is not substantially unyielding, the formula must be rewritten to take account of the actual arrangement. The modulus of elasticity must, of course, correspond with what the test indicates.

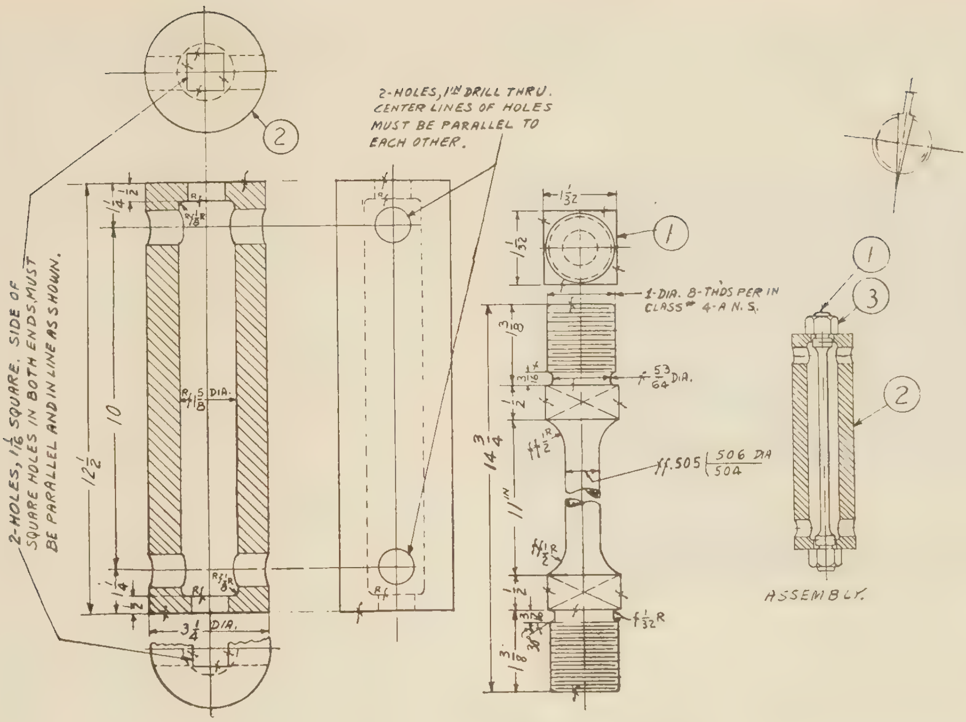

FIG. 1 TEST SPECIMEN, TEST BLOCK, AND ASSEMBLY

Relaxation Tests on 0.35 C Steel K20 at 850 F

BY N. L. MOCHEL,[1] PHILADELPHIA, PA.

INTRODUCTION

THE VARIOUS activities of the Joint Research Committee on Effect of Temperature on Properties of Metals have resulted in the collection of considerable data relative to the effect of high and low temperatures on a specially prepared 0.35 per cent carbon steel, known as material K 20. (See Appendix.) As these accumulated data offer a means of comparing the results secured by several methods of testing, it may be of interest and possible value to add to this accumulation the results obtained from a few simple relaxation tests. The writer has made use of such tests to judge the load-carrying ability of certain bolting steels.

TEST METHOD

Fig. 1 shows the test specimen, the test block, and the assembly. It will be noted that the test specimen is of 0.505 in. diam × 10 in. gage length, and that the threaded ends are made of sufficiently greater section to reduce greatly the stress at those points. Windows are provided in the test block, for purposes of measuring the specimen at the 10-in. gage length on two sides. A square hole is provided in the block and a square section on the specimen, at each end, to prevent twisting of the specimen when tightening the nuts. The gage lengths were fixed by 0.031-in. diam drilled holes rather than punch marks. It is of course necessary that the blocks be made of the same steel as the test specimens, in order to maintain uniform expansion.

Measurement was made with a 10-in. Whittemore strain gage, reading to $^{1}/_{10000}$ in. A standard 10-in. gage was modified by installing points of sufficient length to pass through the windows of the block, into the gage-length holes of the specimen. This instrument is held by two fingers and the thumb of each hand and applied to the work. It is not fastened to it. A standard reference gage is a part of the instrument.

A chart was prepared using the known modulus of elasticity, so that stress could be read directly from elastic or permanent deformation. The length of the specimen was first determined without stress. It was then inserted within the test block and the nuts screwed on by hand. With the test block held hori-

[1] Metallurgical Engineer, South Philadelphia Works, Westinghouse Electric & Manufacturing Co. Mr. Mochel was educated in Pittsburgh and was first employed in 1912 in the inspection department of what was then the Westinghouse Machine Company, later taking charge of the testing of materials. He continued in this capacity after the concern was merged with the Westinghouse Electric & Manufacturing Co. During the War he served with the rank of master engineer in the Engineer Corps of the United States Army in France. In 1920 he assumed his present duties.

Contributed by the A.S.M.E.-A.S.T.M. Joint Research Committee on the Effect of Temperature on the Properties of Steam and presented at the Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, held in New York, N. Y., November 30 to December 4, 1936.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

zontally in a vise, and with one set of windows up, a wrench was applied to one nut and the specimen stretched a predetermined amount. The stretch measurement was made through the top windows, and was then checked on the opposite side through the second set of windows. Fig. 2 shows a block, specimen, and the Whittemore gage.

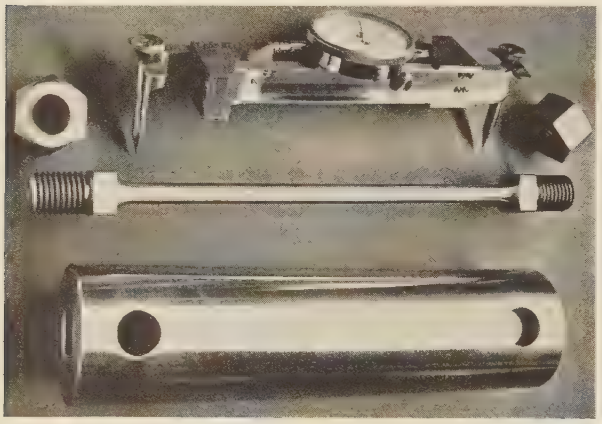

Fig. 2 Block, Specimen, and Whittemore Gage

The assembled blocks and specimens were then stood on end in a special holder provided for the purpose and placed in an electric furnace of cylindrical construction, which was equipped with copper lining, external resistance and double pyrometers arranged to allow the temperature to be closely controlled. Thermocouples were secured directly to the specimens.

Tests may be made in two ways: Specimens may be loaded at some common stress, and one or two specimens removed at desired intervals, cooled, unloaded, their permanent deformation determined, and the curve of relaxation against time plotted; specimens may be stressed in varying amounts and all subjected to temperature for the same length of time, then cooled, and permanent deformation determined. In either case, the measurements before and after the test are made cold, and the amount of permanent deformation indicates the relaxation that took place.

	3	10000	5300	5000	5150	
	4	10000	5000	4700	4850	5000
	5	20000	3900	2300	3100	
	6	20000	4200	5300	4750	3925

Actual service conditions are duplicated, and it is believed that the tests have value from that standpoint. The advantage of being able to take all readings when the specimens are cold will be appreciated. These test methods also provide means for studying the galling of nuts, the use of thread lubricants, and the usefulness of penetrating oils before dismantling.

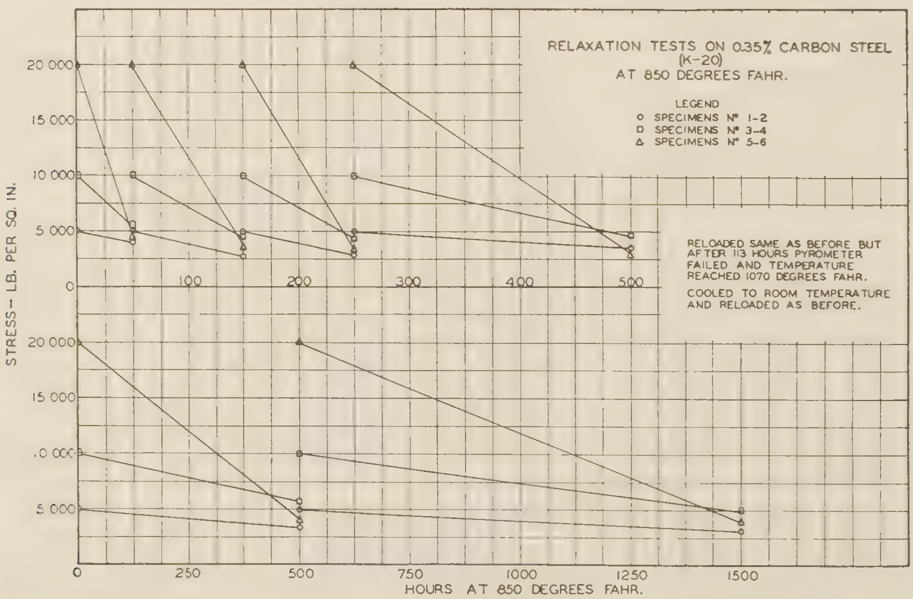

Fig. 3 Results of Relaxation Tests on 0.35 C Steel, Material K20 at 850 F, Using Average Values for Two Sides of Specimens

Tests Made on K20 Steel

Six specimens were prepared from bars K20–6 and K20–11 of the Joint Research Committee material.

Two specimens were stressed to 5000 lb per sq in., two to 10,000, and two to 20,000 lb per sq in. After a period of 50 hr at a temperature of 850 F they were cooled, and the permanent set of each determined. The specimens were then restressed to the same loads as before, held at temperature 100 hr, cooled, and measured. Another cycle of 100 hr and one of 250 hr followed, making a total of 500 hr at temperature.

During the next cycle, after 113 hours at temperature, a pyrometer failure permitted the temperature to reach 1070 F. The specimens were cooled, unloaded, and then reloaded to the same stresses as before.

Additional tests of 500 and 1000 hours were then run.

Fig. 3 shows the results of the tests in graphic form, using average values for two sides of two specimens. Detailed results are given in Table 1.

Discussion

A study of the detailed values shows variations in results beyond those considered good. Such variations have not been as great with other higher-strength steels similarly tested, and it is difficult at the moment to explain these differences. However, it is believed that the test has practical value, and indicates the load-carrying ability of this steel. The effect of the initially applied load is well indicated in the results.

Some few tests were made with a load of 30,000 lb per sq in., and these showed much lower residual stress and erratic results.

Appendix

A full description of the preparation and properties of this material is given in "Short-Time Tensile Tests at 850 F of the 0.35 Per Cent Carbon Steel, Material K20," Report of Subcommittee D of Committee 3, Transactions, A.S.M.E., vol. 58, 1936, paper RP-58-4, pp. 97–101. This report, as stated, covered the short-time tensile tests made on this material, by thirteen cooperating laboratories, to test the code for short-time tensile tests, A.S.T.M. Specification E21-34T.

An appendix to the above report dealt with impact tests at high temperatures on the same material, by two cooperators. Also fatigue tests were covered in this report.

Two progress reports made by the Joint Research Committee have dealt with extended creep tests on the same material:

"Long-Time Creep Tests of 18 Per Cent Chromium, 8 Per Cent Nickel Steel, and 0.35 Per Cent Carbon Steel." Report of sponsored researches at Battelle Memorial Institute, by H. C. Cross and F. B. Dahle, Trans., A.S.M.E., vol. 58, 1936, paper RP-58-3, pp. 91–96.

"Long-Time Creep Tests of 18 Cr 8 Ni Steel K19, and 0.35 C Steel K20." Report to the Joint Research Committee covering a sponsored research project carried out at Battelle Memorial Institute by H. C. Cross and J. G. Sowther. Trans. A.S.M.E., vol. 59, 1937, paper RP-59-5, pp. 441–445.

Appendix I of the 1936 Progress Report covered "General Summary and Comparison of Procedure and Results Obtained on Cooperative Study of Low-Temperature Impact Testing of 0.35 Per Cent Carbon Steel (K20)," Proceedings A.S.T.M., vol. 36, part 1, 1936, pp. 132–142.

Further reports of tests on this steel were made at the Annual Meeting of the A.S.M.E., December 1, 1936.

"Cooperative Creep Tests on 0.35 C Steel K20, at 850 F and 7500 Lb per Sq In." Progress report of the Joint Research Committee on Effect of Temperature on the Properties of Metals, Subcommittee E of Committee 3, C. L. Clark, chairman, Trans. A.S.M.E., vol. 59, 1937, paper RP-59-4, pp. 439–440.

"A Relaxation Test on 0.35 C Steel K20," by E. L. Robinson. Trans. A.S.M.E., vol. 59, 1937, paper RP-59-7, pp. 451–452.

"Relaxation Tests on 0.35 C Steel K20 at 850 F," by N. L. Mochel, Trans. A.S.M.E., vol. 59, 1937, paper RP-59-8, pp. 453–455.

"Constant-Strain-Rate Tests on 0.35 C Steel K20 at 850 F," by A. Nádai and E. A. Davis, Trans. A.S.M.E., vol. 59, 1937, paper RP-59-6, pp. 447–450.

Timber-Connector Construction

By PHILLIPS A. HAYWARD,[1] WASHINGTON, D. C.

The use of timber-connector construction has been acknowledged by authorities as one of the outstanding developments in modern-day use in wood construction. Up to the present time, over nine thousand structures, utilizing some three million board feet of lumber, have been built in which this improved system of timber construction was employed. Structures range all the way from small portable Civilian Conservation Corps camp buildings and low-cost homes, to all-wood radio towers, 326 ft high, and 700-ft timber highway bridges. Wood has repeatedly increased its standing as an engineering material through the use of timber connectors.

This paper tells of the introduction of timber connectors into the United States and gives an analysis of the various types and their possibilities in construction. Particular reference is made to the fact that through their use the strength of wood is increased approximately four times. Important projects in which timber connectors are used are discussed.

TIMBER connectors, recently introduced into American practice, give promise of revolutionizing structural design with timber and restoring its use for many purposes for which it has not been given consideration for a long time. When employed in roof and bridge trusses, diagonal bracing, and other construction requiring end connections of axially loaded members, wood has had its carrying capacity limited in the past by connection details and devices which at times would develop only about 20 per cent of the allowable working load of the members. With timber connectors it is usually feasible to realize in the connections more than 75 per cent of the allowable working load of the members, and the structural efficiency of the material is increased as much as 400 per cent over previous practice.

The expression, "timber connectors," includes a number of devices varying in type and function, practically all of which were invented and employed in Europe during the last two decades. Although American timber resources are far superior to those of the continental countries both in volume and quality, much more consideration is given there to structural use of this material, and timber is often imported from this country to be used in types of structures for which other materials are customarily used here.

With a view to making timber connectors available in the United States, the Department of Commerce, early in 1930, arranged with the various European firms manufacturing or selling these devices to ship a sufficient number of each type to this country for experimental purposes. During 1931 and 1932, tests of these sample connectors were carried on at the United States Forest Products Laboratory, at Madison, Wis., where safe working loads were recommended for each type when employed in the principal American structural species.

It was early recognized that these connectors possessed considerable advantage over the current types of timber-connection details, and in order to bring these advantages to the attention of potential users and to make the connectors generally available, the National Lumber Manufacturers Association, representing the organized lumber producers of the United States, undertook their manufacture and commercial distribution. The more promising of numerous devices were selected and developed in a range of sizes applicable to American standard timber sizes. A great amount of additional testing has been done to arrive at proper working loads for these new sizes in American species, and to afford necessary information on spacing, margins, and the influence of various special factors, such as timber density, conditions of exposure, angle of load to grain, and character of loading.

Three Types of Connectors

Three types of connectors were made commercially available about July, 1933, since which time their employment for structural purposes has increased rapidly. Several million connectors have so far been used in more than 9000 timber structures of many kinds. The United States government has used a great number of connectors in its CCC camp construction program, also on hydroelectric projects, and for various other purposes. State and city governments, public utilities, railroads, and large construction companies are employing connectors in increasing numbers.

The three types of connectors now commercially available are the toothed ring, Fig. 1, known in Europe as the alligator; the split ring, Fig. 2; and the shear plate, Fig. 3, also called the claw plate.

Toothed rings are sharp-toothed corrugated rings of 16-gage hot-rolled sheet steel. When they are to be used in a connection, the members are usually placed in their proper relative position and holes are bored for the bolts which hold the pieces in contact. The members are then lifted apart, toothed rings as specified are placed between them, usually concentric to the bolts, and the bolts are drawn tight, forcing the timbers together and imbedding the toothed rings in the adjacent faces. (See Fig. 4.)

This method of installation sometimes presents difficulties with very dry or dense timbers. In such cases, it is customary to use high-strength, alloy-steel bolts with large, ball-bearing washers and double-depth nuts to draw the timbers together, after which the high-strength bolt is replaced with an ordinary machine bolt. Various forms of clamps, presses, and jacks also are employed to embed toothed rings where the character of the work makes their use convenient. Toothed rings are most often employed where framed structures are to be built up with relatively thin members or where the use of motorized tools to cut grooves or daps for other types is not feasible.

Split-ring connectors are plain steel rings, rectangular in cross section, with a split or break in the perimeter, and are installed concentric to a bolt through the joint. When they are to be used in a joint the bolt holes are first bored according to the plans. Circular grooves one half the depth of the ring parallel to its axis

[1] Chief of the Forest Products Division, Bureau of Foreign and Domestic Commerce, Department of Commerce, in Washington. Mr. Hayward is a graduate of the New York State College of Forestry at Syracuse University, having specialized in lumber utilization and wood technology. For fifteen years, he has been actively associated with the lumber and timber-products industry, and allied fields, both in a technical and nontechnical capacity. As chief of technical research of the former National Committee on Wood Utilization, he assisted in the introduction and use of modern connectors in this country.

Contributed by the Wood Industries Division and presented at the Annual Meeting of The American Society of Mechanical Engineers held in New York, N. Y., December 2 to 6, 1935.

Discussion of this paper should be addressed to the Secretary, A.S.M.E., 29 West 39th Street, New York, N. Y., and will be accepted until September 10, 1937, for publication at a later date. Discussion received after the closing date will be returned.

are then cut with a special tool, concentric to the bolt holes in the adjacent surfaces of the timbers to be connected. The split ring is fitted in these grooves, one half its depth in each timber, and the joint is drawn tight with the bolt. (See Figs. 5 to 7.)

The shear-plate connector is a device for making connections between wood and steel members. Its toothed face is partly fitted and partly embedded in the timber until the opposite, or plane face is flush with the surface of the wood. The projecting

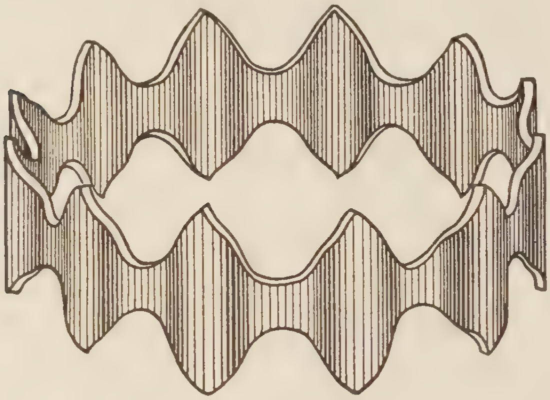

Fig. 1 Toothed-Ring Connector

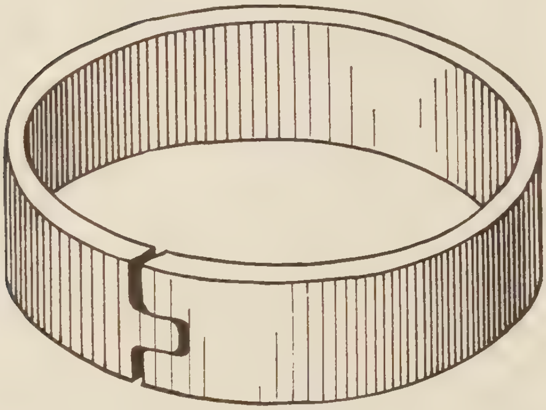

Fig. 2 Split-Ring Connector

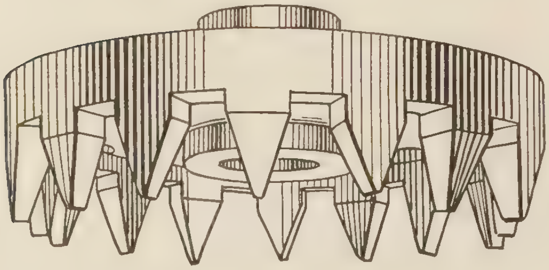

Fig. 3 Shear-Plate Connector

hub on this surface engages a hole in the steel shape or member to which connection is to be made. (See Fig. 8.)

Toothed and split rings are available commercially in several sizes, adapted to varying loads and to different sizes and thicknesses of timber. Shear plates at present are made in one size only.

Some recent work has been done on the solution of structural problems requiring the use of other types of timber connectors. A clamping plate has been developed for use between bridge ties and guard rails or stringers, between trestle caps and the tops of piles, and other points where lateral movement of one timber on another must be prevented. Flat and curved spike grids have been developed for use between bracing and piles or posts in marine structures and trestles. These connectors will soon be commercially available.

Possibilities of Timber Construction

The variety of uses to which connectors have been put is most remarkable, considering that they have been available commercially for only about two years. The extent to which timber construction employing them is likely to increase and spread depends considerably upon the extent to which architects, engineers, and builders are able to divest their minds of a widely disseminated misapprehension about timber construction and to view in an unbiased way the inherent possibilities of the material as influenced by: (1) Better and more dependable structural grades; (2)

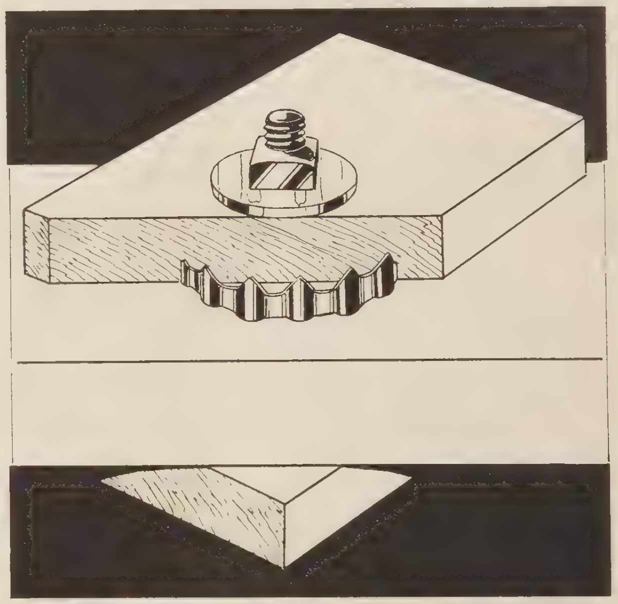

Fig. 4 Cutaway Piece in Assembly at Right Shows Toothed Ring With Half Its Depth Imbedded in Center Timber and Half Projecting Into Side Member

thorough and reliable preservative treatment where this is advisable; (3) stronger, simpler, and more economical designs available through the use of connectors.

Through the organized effort of the lumber manufacturers, working in collaboration with such groups as the American Society for Testing Materials, the American Railway Engineering Association, and the American Society of State Highway Officials, and with the close cooperation of interested government agencies, there has emerged during the last ten years a system of structural grading for lumber which admits of definite working stresses being assigned with confidence to each grade and species. The practice is rapidly increasing, of marking each piece so graded, at the mill, with its allowable unit stress in bending or compression. Where this is not done a certificate of inspection, guaranteeing the structural grade of the material, is usually obtainable upon request.

The advantages of preservative treatment of wood are increasingly recognized where the service conditions and the charac-

ter of the material used make decay a hazard. There is accumulating, as time goes on, a greater volume of evidence as to the effectiveness of preservative treatment in certain fields where it has long been employed, from which results of its use in other situations can be predicted. Recognition is also being given to the greater service life of wood selected from the various species and grades available to meet special conditions

The foregoing with other aspects of wood utilization, constitute a vast volume of information not well-taught in technical and architectural schools and until recently not readily available in published literature. There have been issued recently, however,

Fig. 7 Cutting Grooves for Split Rings With Portable Drill

Fig. 8 Assembly of Steel Shear Plates Used in Foot of Radio Tower

a number of comprehensive booklets on wood utilization which should be in the hands of every student of the building professions and trades as well as those now practicing them.

Due to the lack of complete information on timber design and satisfactory control of quality, there has been a tendency in the past to penalize the material with unnecessarily low working stresses and to employ uneconomic sizes and grades. There also

has been an inclination to be content with less thorough inspection and supervision of fabrication and erection than is customary with other construction materials, and designers have tended to discount this prospect by overconservative designs. It is a truism, however, that lack of engineering design and supervision cannot be discounted safely even by the most conservative of working stresses, and the more recent tendency, stimulated by the introduction of timber connectors, is to apply these precautions in building to wood as well as other materials. Using principles of design and working stresses consistent with these precautions, it frequently develops that the same structural work is accomplished with a pound of timber as with a pound of steel.

Uses in Industry

Timber-connector construction is finding an increasing use in oil-industry structures. No oil derricks have as yet been built of this type, but several designs now in preparation indicate the feasibility of this type of structure. Numerous casing racks, oil-derrick foundation structures, and tank supports using connectors have been built in the Texas and Louisiana fields.

Several tank towers have been built of timber-connector construction, and this construction is particularly applicable in cases where heavy loads are to be supported, as timber by reason of its peculiar physical characteristics affords column load capacity in a very economical form.

Large numbers of connector-built roof trusses and roof arches are in use in spans ranging from the 20-ft width of the CCC camp buildings to 100- and 120-ft airplane hangars, garages, and ice-skating rinks. It is reported that over 80 linear miles of portable CCC camp buildings were built by the United States government during the last year in which an ingenious combination of portable roof panels and additional pieces were used to form Fink trusses connected with $2^1/_2$-in. split rings. The same type of building is now being adapted by the National Lumber Manufacturers Association to numerous other purposes, such as garages, farm buildings, summer camps, and low-cost dwellings.

The earliest timber-connector structure built in this country, so far as is known, was an 80-ft through-railway bridge for E-60 loading, constructed by the Weyerhaeuser interests on one of their logging railroads. This proved thoroughly satisfactory and subsequently another bridge of the same type was built. Since the general introduction of connectors into American practice, a considerable number of bridges have been built ranging from small temporary bridges of limited span and loading to a 180-ft arched bridge on the Pacific Coast Highway near Monterey, California, known as the Dolan Creek Bridge. This structure required 357,000 ft of timber and over 15,000 connectors. It was designed for the maximum highway loading. Timber-connector construction has also been utilized for stiffener trusses for suspension bridges in spans up to 209 ft.

The United States Army Engineers have employed timber connectors in building crib work for cofferdams on hydroelectric projects, both in the South and in the far West. Interesting examples of special uses include the use of toothed rings to stiffen the ribs of ice breakers built for the United States Coast Guard and the insertion of toothed rings between pile heads and caps in timber trestles, and between the ties and stringers and guard timbers in open and ballast deck trestles. Toothed rings are used for splicing, in joists and rafters in fire-damaged buildings, or where greater load capacity is required in a floor structure already in place. Large numbers of both types were used in strengthening and repairing California school buildings damaged by earthquakes in that state about a year ago. The United States government and several state governments have employed split-ring connectors in forest lookout towers ranging up to 100 ft in height, and one radio broadcasting tower 326 ft in height was constructed recently at Richmond, Virginia, entirely of timber-connector construction.

Prefabrication

One of the interesting developments in timber construction, made feasible by connectors, is the complete shop detailing of wood framing in the same fashion as is customary for steel fabrication. On numerous occasions, members shop-fabricated according to the usual details, have been transported several hundred miles and erected in the same fashion as is customary with steel.

One problem of the lumber industry in making the new construction development available generally to specifying consumers, architects, engineers, and builders, is the lack of fabricating concerns in the wood industry similar to those which operate steel-fabricating shops. The number of firms prepared to undertake such fabrication in timber is increasing rapidly, however, and there is also an increasing number of consulting engineers and architects throughout the country who are becoming familiar with the possibilities of timber-connector construction, so that in time arrangements for this type of service can be made as readily as is the case with steel.

Fabrication and Erection Costs

Experience on various jobs taken in conjunction with the known costs of timber connectors, hardware and suitable lumber indicate that the cost of connector structures in place, will not at the present price scale exceed 4 cents per pound and in many cases will fall much below that figure.

Acknowledgment

The author is greatly appreciative of the assistance given by Messrs. Frank Cartwright and Peter Landsem of the Timber Engineering Company, Washington, D. C. Credit is also given to this company for the illustrations shown in the accompanying text.

Discussion

Casting or Welding in Machine Design[1]

J. F. Lincoln.[2] Although the author's paper contains valuable and interesting information on the relative merits of castings and structures made from arc-welded steel, the writer believes he has not gone far enough into the subject and has thought in terms of what has occurred in this field rather than in terms of what should occur. The fundamentals of the problem are as follows:

Structural steel is two and one-half times as stiff and five times as strong as cast iron, yet it costs approximately one third as much per pound on the average. Arc welding makes it possible to join structural steel together at a very low cost so as to give a joint equal to the strength of the steel itself.

The writer is of the opinion that if a mechanical engineer with these facts at hand cannot produce structures in general very much cheaper with welded steel than with cast iron, then the difficulty is not with the process but rather with the engineer. At least 75 per cent of all castings which are now made can be redesigned using welded structural steel at a saving in cost and an improvement in the product. The method of accomplishing this is not obvious in all cases, but that is a problem with which the engineer must contend. Were it obvious, a great profession would be discarded.

Author's Closure

The author agrees with Mr. Lincoln that inasmuch as the modulus of elasticity of cast iron is approximately 12,000,000 and that of steel 30,000,000 the stiffness of steel for a given section is $2^1/_2$ times as much as that of cast iron. He realizes, however, that to increase the stiffness of a given section by $2^1/_2$ times requires an increase in depth of section of less than 40 per cent. As it may be entirely feasible in any given case to provide the required depth of section in cast iron to give the necessary stiffness, the advantage of the high modulus of elasticity of steel may not always be a controlling factor.

When we are considering structural steel and make the statement that steel is five times as strong as cast iron we must be thinking of ultimate strengths and furthermore, of a very high grade of structural steel and an extremely poor grade of cast iron. High-test cast iron is being produced regularly with several times the strength of the poor grade evidently meant in the five-to-one comparison. In machine design, where true surfaces and alignments must be maintained, we are interested in the yield point of the material rather than the ultimate strength. This figure is about 30,000 lb per sq in. for ordinary structural steel. The yield point and ultimate strength of any particular grade of cast iron are close together, which is another way of saying that cast iron is a brittle material. Ordinary grey cast iron has a strength of 20,000 to 25,000 lb per sq in. and the higher grades have a strength of 30,000, 40,000, and even more. It may transpire therefore that when the better grades of cast iron are used, they may be, from the standpoint of machine design, even stronger than ordinary structural steel.

Further, it is the author's feeling that it is passing too hurriedly over the matter of cost to state that structural steel costs approximately one third as much a pound as cast iron. The quantity price for structural steel may be roughly two cents a pound. According to this formula the average cost of cast-iron castings would be six cents a pound. Inasmuch as the cost of iron at the spout may be in the neighborhood of one cent a pound the cost per pound of the completed casting may easily be much less than six cents a pound if sections are heavy and the activity of the part is such as to justify high-grade pattern and foundry equipment. It should be borne in mind also that the two-cents-a-pound structural material must be cut to size, assembled with pieces in proper relation, and the welding operation performed before it is in form comparable to the completed casting. With the expense of these operations added, the whole cost divided by the number of pounds of the completed article will show a cost per pound considerably more than two cents and probably in the neighborhood of ten or twelve cents on the average. In addition to this, if machining operations are contemplated it will be found that the expense of machining the welded-steel structure will exceed the cost of machining the cast-iron casting.

Mechanical engineers undoubtedly have something yet to learn about the application of arc welding in the design of machine structures but the author feels constrained to submit that in perusing this study they will find necessary a much more detailed consideration of the relation of the casting and welding methods of fabrication than would be inferred from a reading of Mr. Lincoln's brief presentation of the "fundamentals" of the problem.

A Theory of Paper Drying[1]

M. A. Golrick, Jr.[2] The similarity between paper-drying and cloth-drying systems is apparent from a study of the theory and derivation of the equations presented by the authors. The application of drying cans to fabrics has been truly a rule of thumb development as far as the number for a given installation is concerned. In addition, the width has been generally standardized so that uneconomically wide cans are frequently used to dry narrow fabrics in plants having sufficient volume of these fabrics to warrant a more economical installation. The correct width of can as a single consideration is easily arrived at, but the entire balance is certainly worthy of study to have a better mathematical analysis than at present.

The suggestion of developing formulas for cloth drying, resulting from the development of the theory of paper drying as presented by the authors, holds interesting possibilities for further application to fabrics as well as paper. The closest analogy is that of cans being used to dry both materials, and the theory of moisture removal would be on a similar basis.

The outstanding difference between cloth and paper drying is that paper-drying systems use a felt to hold the paper fibers or the sheet of paper as it becomes dried to the surface of the drying cans. In fabric drying, the cloth is its own blanket. The only cloth-drying systems that use a blanket are the Palmer finishing machines. These are essentially much slower in drying cloth than the regular open textile can systems.

[1] Published as paper PRO-58-6, by E. Cowan and B. Cowan, in the November, 1936, issue of the A.S.M.E. Transactions.

[2] Plant Engineer and Production Manager, Dutchess Bleachery, Inc., Wappingers Falls, N. Y. Mem. A.S.M.E.

The effect of drying paper may have a similar effect of case hardening the fibers to that which it has on drying on cans certain textile fabrics, rayon in particular. The contact with a can surface gives a harshness to fibers which cannot be successfully removed in later processes. The rate of drying may have considerable influence on the degree of harshness, and possibly paper manufacturers have a better knowledge of the method of correcting this influence than textile finishers. Considerable investigation is being made along these lines at the present time.

The large difference in texture between paper and cloth would minimize the importance of the rate of steam escape from the sheet of paper which is the first factor X, that is, the maximum permissible rate of evaporation in pounds of water per square foot of sheet per hour. The structure of cloth is a series of threads in varying combinations of weaves but having openings, which distinguishes cloth from paper. Paper does not have its fibers assembled in the same manner as do cloth fibers or yarn, and this inherent difference might have considerable weight in considering its balance of the factor X in the formulas.

One other difference which is easily discernible is the greater variation of thickness of textile fabrics as compared with paper. The thickness of cloth of usual type may vary from 0.008 in. to novelty or waffle cloth of $^3/_8$ in. thickness. A further difference in the latter types of cloth as compared to paper would be the entire lack of uniform surface contact. In the case of fabrics such as corded or float fibers, it would only be the top fibers in direct contact for half the cans in the drying system. In exceptionally thick fabrics such as waffle cloth, only the top threads would have can contact on one half the cans, leaving an air space of 0.25 in. or more between the can surface and the intervening fabric.

In general, the theory of paper drying might well be applied to cloth drying with due consideration to these previously mentioned factors. The cloth-drying systems in use have been expanded for such a variety of fabrics that in most cases the customer has specified the number of cans or cylinders and has been content with the result. As in paper drying, the control of speed and steam pressure has generally sufficed for practical purposes. Investigation of this theory of paper drying as applied to cloth may indicate other factors of interest to paper manufacture.

A lack of complete knowledge of the paper industry and its problems prevents a more extended discussion along these lines. However, it is hoped that these suggestions will stimulate discussion and bring about suggestions not only on paper drying but also on textile drying. Rule-of-thumb methods should be replaced with definite formulas and the authors have taken a constructive step in the right direction.

Welding Design[1]

H. C. Perkins.[2] The author describes a very interesting application of the principles of elementary strength of materials to a relatively new field. He makes it clear that the critical stress usually occurs at the minimum or throat section of a fillet weld, and that to a first approximation this critical stress may be regarded as uniformly distributed, or in cases such as bending of a fillet weld where a second approximation is required, the stress may be regarded as proportionally distributed. He also states that one of the first principles in the design of fillet welds is the "generally accepted assumption" that whenever possible "the stress on a throat section is principally a normal tensile stress."

[1] Published as paper MSP-58-1, by Charles H. Jennings, in the October, 1936, issue of the A.S.M.E. Transactions.

[2] Assistant Professor in Mechanics, Sibley School of Mechanical Engineering, Cornell University, Ithaca, N. Y. Mem. A.S.M.E.

These assumptions are generally consistent with those found in elementary texts on strength-of-materials, but the methods by which the author converts these assumptions into design formulas do not always conform to the fundamental principles taught in such texts.

Consider, for example, the derivation of the author's Equation [3] for stress at the throat section of the transverse fillet welds shown in Fig. 4 of the paper. As shown in Fig. 1 of this discussion the action line of the load makes a 45-deg angle with the throat section so the ratio of the force P to the area $(0.707hl)$ of that section is certainly not a tensile stress. Such a procedure is wrong in principle and leads to an underestimate of the stress.

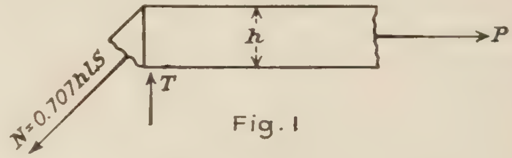

Fig. 1

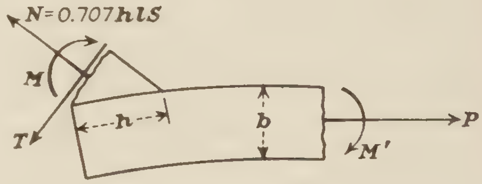

Fig. 2

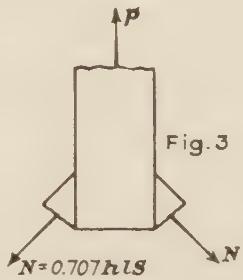

Fig. 3

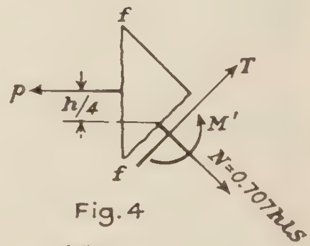

Fig. 4

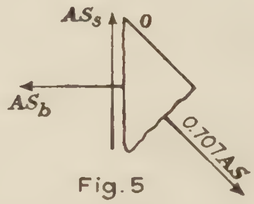

Fig. 5

Fig. 1 of this discussion shows the plate held in equilibrium by the load P, a tensile force $N = 0.707hlS$ normal to the throat section, and a transverse pressure T between plates as described by the author. If the action line of T is near the end of the plate, as shown, these forces are sufficient to satisfy the equations of equilibrium, in which case the throat section may be regarded as free from bending and shear.

Summing components in the direction of P

$$P - 0.707(0.707hlS) = 0$$

or

$$S = \frac{2P}{hl} \qquad [1]$$

Stresses obtained by this equation are about 40 per cent greater than those obtained by the author's Equation [3].

The derivation of the author's Equation [6] for maximum unit tensile stress in the throat section of the fillet weld of Fig. 6a

of the paper again involves some doubtful approximations. In this case, there is a fillet weld on only one side of the plate so, as the author states, "a bending moment resulting from the joint eccentricity must be considered."

It is in estimating the amount of this moment that one difficulty arises. The load being eccentrically applied, both fillet and plate may be bent. The greater the moment M' carried by the plate, the smaller must be the moment M carried by the fillet.

If the plate is relatively stiff or is laterally supported against bending, the fillet will bend very little if at all, and approximately $M = 0$. The throat section will then be stressed in tension and shear only. The average unit tensile stress on that section may be calculated from Fig. 2 of this discussion by summing components parallel to N, that is

$$0.707\ hls - 0.707P = 0$$

or

$$S = \frac{P}{hl} \qquad [2]$$

Results obtained by Equation [2] of this discussion are about 40 per cent less than those obtained by the author's Equation [4] which he again derives by dividing the force P by the area of a section at 45 deg to its action line.

If the plate is slender and bends easily the fillet may carry practically all of the bending moment, and

$$M = P\left(\frac{b}{2} + \frac{h}{4}\right)$$

Below the yield stress, the corresponding bending stress, formulated in terms of the section modulus of the throat section

$$Z = \frac{(0.707h)^2}{6}\, l = \frac{h^2 l}{12}$$

is

$$S_b = \frac{12M}{h^2 l} = \frac{3P(2b + h)}{h^2 l} \qquad [3]$$

The maximum tensile stress is obtained by adding the stresses given by Equations [2] and [3] of this discussion, or

$$S = \frac{P}{hl} + \frac{3P(2b + h)}{h^2 l} = \frac{4P}{hl}\left(1 + \frac{3b}{2h}\right) \qquad [4]$$

Equation [4] of this discussion is not comparable with the author's Equation [6]. However, if it be assumed that the moment is divided between plate and fillet in an arbitrary manner, that is, $M' = Pb/2$ and $M = Ph/4$, then the maximum elastic stress on the throat section is approximated fairly well by the author's Equation [6]. Adding bending stress to the average unit tensile stress as given by Equation [2] of this discussion, then

$$S = \frac{P}{hl} + \frac{12}{h^2 l}\frac{Ph}{4} = \frac{4P}{hl} \qquad [5]$$

This expression gives elastic stresses about 17 per cent greater than the author's Equation [6] which he derives by assuming that all of the fillet has passed the yield point, and that the bending stress is therefore uniform rather than proportionally distributed. The assumption that the bending moment is divided between plate and fillet in such an arbitrary manner is not likely to be consistent with the facts, so it is surprising that the author's Equation [6] should agree at all with experimental results.

The author's derivation of his Equation [8] is another example of faulty procedure. Assuming as usual that throat sections are subjected primarily to normal tension, let Fig. 3 of this discussion represent the plate held in equilibrium by a tensile load P and by tensile forces $N = 0.707hlS$ normal to the throat sections. These forces are sufficient to satisfy the equations of equilibrium. Summing components in the direction of P

$$P - 2(0.707)0.707hlS = 0$$

or

$$S = \frac{P}{hl} \qquad [6]$$

Stresses obtained by this equation are about 40 per cent greater than those obtained by the author's Equation [8].

Again, if the welds of Fig. 9 of the paper be analyzed by the method indicated in Fig. 1 of this discussion, the results will be about 40 per cent greater than those given by Equations [9] and [10] of the paper, as shown by the two following equations

$$S = \frac{a}{b + a}\,\frac{2P}{hl} \qquad [7]$$

and

$$S = \frac{b}{b + a}\,\frac{2P}{hl} \qquad [8]$$

Methods of computing stress in transverse fillet-welded joints subjected to bending are as the author says, approximate. The formulas he derives may agree fairly well with experiment but it is unfortunate that those formulas do not follow logically from his assumptions. Consider particularly the author's Equation [16] for maximum normal stress on a throat section when the load is a bending couple M as shown in Fig. 12a of the paper. The author assumes that the moment M is counteracted by a couple composed of forces p acting at the centers of the vertical fusion zones of the welds, shown as ff in Fig. 4 of this discussion, and therefore the moment $M = p(b + h)$. The load p on one weld is therefore assumed to act as shown in Fig. 4 of this discussion, from which it follows that the throat sections are stressed in tension, shear, and bending as shown in the figure.

Summing components parallel to N in Fig. 4 of this discussion, solving for average unit tensile stress S_1 and substituting for p in terms of M, then

$$0.707hlS_1 - 0.707p = 0$$

$$S_1 = \frac{p}{hl} = \frac{M}{hl(b + h)} \qquad [9]$$

But the force p has a moment $M' = ph/4$ about the central axis of the throat section, corresponding to maximum bending stress

$$S_b = \frac{ph}{4}\,\frac{12}{h^2 l} = \frac{3M}{hl(b + h)} \qquad [10]$$

The maximum normal stress upon the throat section is then equal to the sum

$$S = S_1 + S_b = \frac{4M}{hl(b + h)} \qquad [11]$$

If the author's Equation [16] gives results in fair agreement with experiment, Equation [11] of this discussion, which yields results 180 per cent greater, will be considerably in error.

Lacking such agreement, the author's assumption that M is counteracted by forces p acting at the center of the vertical fusion zones must be abandoned. A more familiar type of calculation leads to a simpler result with fewer doubtful assumptions. The

section modulus of both fusion zones together, about the central axis of the plate is

$$\frac{I}{c} = \frac{(b + 2h)^3 l - b^3 l}{12 \frac{b + 2h}{2}} = bhl + \text{terms in } h^3, h^4, \text{etc.}$$

The corresponding maximum bending stress is

$$S_b = \frac{Mc}{I} = \frac{M}{bhl} \qquad [12]$$

The stress near the surface of the fillet must be a simple tension parallel to the surface so the bending stress S_b at the outer edge O of the fusion zone must be accompanied by an equal shearing stress $S_s = S_b$ as shown in Fig. 5 of this discussion. Summing components in the direction of S_b

$$AS_b - (0.707)(0.707)AS = 0$$

and solving for the normal tension S

$$S = 2S_b = \frac{2M}{bhl} \qquad [13]$$

which yields results about 40 per cent greater than the author's Equation [16]. The only difference in case the load is a force P, is in the substitution of PL for M, whence

$$S = \frac{2PL}{bhl} \qquad [14]$$

which yields results about 40 per cent greater than the author's Equation [18]. Equation [14] of this discussion is very much simpler in form than the author's Equation [18], and it has a better technical basis.

There are some interesting steps in the author's derivation of his Equation [21] for maximum normal stress in longitudinal fillet welds subjected to bending. In the first place the section modulus for an axis inclined to the section is an unusual idea. In the second place this procedure leads to numerically incorrect results. Proceeding along more familiar lines, the section modulus of the two fusion zones next the support is, for both zones together

$$\frac{I}{c} = \frac{2hl^2}{6} = \frac{hl^2}{3} \qquad [15]$$

corresponding to maximum unit bending stress

$$S_b = \frac{Mc}{I} = \frac{3PL}{hl^2} \qquad [16]$$

The stress near the surface of the fillet must be a simple tension S parallel to the surface, as shown in Fig. 5 of this discussion, accompanied by vertical shear (perpendicular to the plane of the figure). The bending stress S_b at the outer edge O of the fusion zone must be accompanied by an equal lateral shearing stress $S_s = S_b$ as shown in Fig. 5 of this discussion. Summing components in the direction of S_b and solving for the normal tension S as before

$$S = 2S_b = \frac{6PL}{hl^2} \qquad [17]$$

which yields results 40 per cent greater than the author's Equation [21].

The author's Equation [26] is derived from his Equations [16] and [21] in a very clever manner but, unfortunately, both of these equations are incorrect so Equation [26] is of doubtful value. It is probably better to proceed along familiar lines anyway. The section modulus of the fusion zone is

$$\frac{I}{c} = \frac{(b + 2H)^3(l + 2h) - b^3 l}{12 \frac{b + 2h}{2}}$$

If h be regarded as relatively small, this expression may be expanded and simplified by dropping terms in h^3 and h^4. Then

$$\frac{I}{c} = \frac{bh}{3}(3l + b + 4h) + \ldots$$

Using this value, the maximum bending stress on the fusion zone is

$$S_b = \frac{Mc}{I} = \frac{3M}{bh(3l + b + 4h)} \qquad [18]$$

Calculating the corresponding normal stress S from Fig. 5 of this discussion

$$S = 2S_b = \frac{6M}{bh(3l + b + 4h)} \qquad [19]$$

This Equation [19] is very much like the author's Equation [26] in form but yields results about 40 per cent greater.

The author's Equation [32] also yields results which are about 40 per cent in error. This is another case in which little is gained by departing from familiar methods of procedure. The section modulus about a diameter of a hollow circular section with an outside diameter $(D + 2h)$ and an inside diameter D, as shown in Fig. 15 of the paper, is

$$\frac{I}{c} = \frac{\pi}{32}\frac{(D + 2h)^4 - D^4}{(D + 2h)} = \frac{\pi Dh}{4}(D + h) + \ldots$$

The first term, alone, corresponds to the value used by the author.

The maximum bending stress on the fusion zone is then

$$S_b = \frac{Mc}{I} = \frac{4M}{\pi Dh(D + h)}$$

corresponding to normal stress S from Fig. 5 of this discussion, or

$$S = 2S_b = \frac{8M}{\pi Dh(D + h)} \qquad [20]$$

which yields results 40 per cent greater than the author's Equation [32].

The author's Equation [37] is derived from his Equation [3] which yields results 40 per cent too low. Therefore, Equation [37] of the paper should be corrected to read

$$S = \frac{2P}{2hl + h_1 l_1} \qquad [21]$$

To summarize the discussion, the writer recommends the following, after corresponding changes have been made in Figs. 19, 20, 21, and 22 of the paper:

For calculating stress in a lap joint with a single transverse weld, substitute the writer's Equation [1] for the autbor's Equation [3].

For calculating stresses in welds on one side of a plate in tension and in which bending is prevented, substitute the writer's Equation [2] for the author's Equation [4].

For calculating stresses in welds on one side of a plate in which bending is carried by the weld, substitute the writer's Equation [4] for the author's Equation [6].

For transverse welds on both sides of a plate in tension, substitute the writer's Equation [6] for the author's Equation [8].

For calculating stresses in double-welded lap joints, substitute the writer's Equation [7] for the author's Equation [9].

For double transverse welds in bending, substitute the writer's Equation [13] for the author's Equation [16], and also the writer's Equation [14] for the author's Equation [18].

For double longitudinal welds in bending, substitute the writer's Equation [17] for the author's Equation [21].

For transverse and longitudinal welds subject to bending, substitute the writer's Equation [19] for the author's [26].

For a ring weld at the end of a circular bar in bending, substitute the writer's Equation [20] for the author's Equation [32].

For butt weld with cover plates attached by transverse welds and subject to tension, substitute the writer's Equation [21] for the author's Equation [37].

Author's Closure

The author pointed out in the paper[1] that there was a surprising lack of agreement among authorities in regard to the proper method of making stress analyses. Also, he pointed out that many of the equations given were those that are now commonly accepted by the trade and that they were only approximate equations justified because of their fair agreement to actual test results. In other words, if the tensile strength of the weld metal is known, the ultimate strength of the welds, calculated from the formulas given, should give results approximately equal to the ultimate strength of the weld metal.

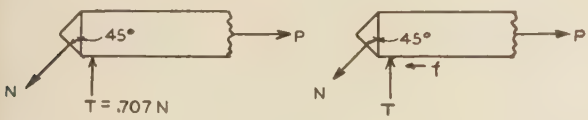

Fig. 6

Mr. Perkins has criticized the formulas in the writer's paper and has in turn developed formulas also open to criticism.

Referring to the determination of the stress in a simple fillet weld Mr. Perkins has used a free-body diagram, as shown in Fig. 6*a* of this discussion which assume the plates to be in contact. If there is a force T present, there must also be a friction force f present as shown in Fig. 6*b* of this discussion. The value of the friction force may vary over a wide range, depending upon the surface conditions of the plates. If the friction force is assumed to be $^1/_4\,T$, then the equation for the weld stress will be: $P = (T/4) + 0.707N$, where $T = 0.707N$. Therefore, $P = 0.707N\ (1.25)$, or $N = P/[(0.707)(1.25)]$. The stress $S = N/0.707hl = P/[(0.707)^2hl\ (1.25)]$, or

$$S = 1.6\ P/hl \qquad [22]$$

Equation [22] of this discussion is in closer agreement with Equation [7] of the paper than it is with Equation [1] of this discussion as given by Mr. Perkins.

Another method of analysis has been used by L. W. Schuster[3] which consists of resolving the force P into tangential and normal components, as shown in Fig. 7 of this discussion, and assuming the resultant principal stress at the weld throat to be the critical stress.[4] If it were assumed that the welded plates are not in contact with each other so that the force T, which is shown in Fig. 6 of this discussion, is not present (this case sometimes occurs in practice) then the stress at the weld throat will be

$$S = \frac{1.618\ P}{hl} \qquad [23]$$

This equation compares closely to Equation [22] of this discussion, and does not differ greatly from the conventional equation $S = 1.414\ P/hl$.

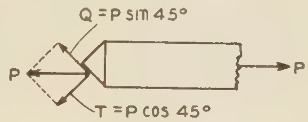

Fig. 7

As mentioned before, all of these equations are only approximations. Consequently, the choice as to which one to use depends upon their agreement with actual test results. Tests made on fillet welds deposited with bare type electrodes that produce weld metal with an ultimate strength of 55,000 lb per sq in. and 10 per cent elongation in 2 in. are given in Table 1 of this discussion.

TABLE 1 TENSILE TESTS ON FILLET WELDS

Size of welds	Ultimate load, lb 2P	Stress lb per sq in. $S = \frac{1.414P}{hl}$	$S = \frac{1.618P}{hl}$	$S = \frac{2P}{hl}$
$^1/_4 \times 2^1/_2$ in.	44600	50700	57800	71400
$^1/_4 \times 2^1/_2$ in.	42800	48400	55500	68500
$^1/_4 \times 2^1/_2$ in.	39500	44800	51200	68100
$^1/_4 \times 2^1/_2$ in.	47700	56400	64400	79500
$^1/_4 \times 2^1/_2$ in.	41200	46600	53200	65900
Average	...	49400	56400	69600
$^3/_8 \times 2^1/_4$ in.	60700	50900	58400	72000
$^3/_8 \times 2^1/_4$ in.	57800	48500	55500	68500
$^3/_8 \times 2^1/_4$ in.	56200	47100	53800	66500
$^3/_8 \times 2^1/_4$ in.	54800	45800	52500	65000
$^3/_8 \times 2^1/_4$ in.	60100	50400	57600	71300
Average	...	48500	55500	68700

Note: All welds had very good fusion.

From these data it is seen that the author's proposed equation $S = 1.414\ P/hl$ gives fairly good agreement, Mr. Perkins' equation $S = 2\ P/hl$ gives quite high results, while the third equation $S = 1.618\ P/hl$ gives the closest agreement.

The fact that the conventional equation $S = 1.414\ P/hl$ gives close agreement to test results and is used almost universally in this country for computing stresses in fillet welds there seems to be justification for its continued use, even though the third method discussed appears to be more accurate.

Considering the other equations discussed by Mr. Perkins it will be noted that although a different method of analysis was used in many cases the results obtained always varied by about 40 per cent. In other words, if a similar method had been used to analyze the simple fillet weld the results obtained in both cases would have been essentially the same.

The author greatly appreciates Mr. Perkins' discussion because it indicates that some serious thought is being given to the problem and it is only in this way that a standard method of calculating weld stresses can be developed.

Experimental Determinations of the Flow Characteristics in the Volutes of Centrifugal Pumps[1]

A. J. Stepanoff.[2] The results of tests presented in this paper are of particular interest, because they were based on large-sized modern high-efficiency pumps. A great many previous publications on centrifugal pumps have dealt with such small obsolete designs that conclusions based on tests have been entirely mis-

[1] Published as paper HYD-58-4, by R. C. Binder and R. T. Knapp, in the November, 1936, issue of the A.S.M.E. Transactions.

[2] Assistant Chief Engineer, Byron Jackson Company, Berkeley, Calif. Mem. A.S.M.E.

leading, and certainly were of little interest to the commercial designer of centrifugal pumps or to the industry.

The writer does not agree with the authors in some of their analyses and conclusions. For instance, the explanation of two peaks in the velocity distribution across the volute at the impeller discharge by the pumping effect of the outside walls of the impeller shrouds, seems unreasonable, and the improvement of pump efficiency by such "energy pump" is hardly possible. It should be remembered that all low-velocity water in the space between the impeller and case walls, which is acted upon by the impeller shrouds, comes from high-velocity and high-pressure sections of the volute into the low-velocity and low-pressure region at the case wearing ring. Thus, no recovery of the velocity into pressure takes place, and hence there can be no question that circulation of water in the space between the impeller shrouds and pump case results in a net loss of energy.

Higher efficiency of pumps, with larger clearances between the case walls and impeller shrouds in modern pumps, is accounted for by the use of more efficient impeller profiles with less abrupt change in the direction of flow in the impeller, requiring wider volute cases. Also, it has been proved by special tests that the losses at the impeller discharge are smaller when discharging into a body of revolving water than against the stationary walls of the pump casing. The greater clearances between the case and impeller also have the advantage of the possibility of using several impellers of different widths and diameters in the same case.

As far as the disk-friction loss is concerned, Le Conte's[3] and Gibson's[4] tests tend to prove that this loss is greater with larger clearances.

The following explanation of the two peaks in the velocity distribution at the impeller discharge across the volute is suggested:

It has been pointed out by several investigators that in a centrifugal-pump impeller there is circulation within the impeller channel superimposed on the outward flow through the impeller. With nonviscous fluids, as a result of the impeller rotation, only relative circulation within the impeller cells will result, and no head will be produced. With actual liquids, the more this circulation is suppressed by the impeller walls and vanes, the higher is the head produced by the impeller. Thus, impellers with a greater number of vanes generate higher heads. Also, for the same impeller diameter and number of vanes, narrow impellers will develop a higher head than wide impellers. Since the centrifugal component of the total head is the same for all points of the same diameter, this extra head can be only in the form of kinetic energy. The two peaks in the velocity distribution at the impeller shrouds are caused by the stabilizing effect of the shrouds on the flow in the impeller, whereby the circulation within the impeller channel is suppressed to a greater degree at the shrouds than at the middle of the impeller.

As an illustration of this point of view, the writer can mention some tests performed at the plant of the Byron Jackson Company on double-suction, horizontally split pumps. One test was conducted on a 36 in. pump which had an impeller diameter of 42 in., and a width of 12.5 in. The other test was conducted on a 10-in. pump which had an impeller diameter of 11 in. and a width of 2.25 in. Both of these impellers had the middle impeller wall extended to the full diameter of the impeller. The velocity distribution across the volute had three clearly marked peaks. Evidently the middle peak cannot be explained by the pumping effect of the outside impeller shrouds.

[3] "Hydraulics," by Joseph N. Le Conte, McGraw-Hill Book Company, New York, N. Y., 1926, p. 333.

[4] "Hydraulics and Its Applications," by A. H. Gibson, D. Van Nostrand Company, Inc., New York, N. Y., 3d edition, 1925, p. 190.

The uniform velocity distribution between the impeller vanes, as shown in Fig. 10 and Fig. 14 of the paper, seems improbable, particularly for a low-capacity point, when a considerable portion of the power input is wasted in turbulence. In modern high-efficiency pumps, impeller-vane tips at the discharge are made nonactive, or are so shaped that no head is generated by this portion of the vanes, thus providing a short transition path from the impeller to the volute where velocity can equalize. However, there is sufficient evidence, such as impeller pitting, wear marks, and reliable pressure-distribution tests,[5] within the impeller channels, to indicate that there is more velocity variation within the impeller passages than was recorded in the authors' tests. The causes for possible inaccuracy of observation were pointed out by the authors.

(Discussion following was submitted jointly with the discussion of the paper by R. T. Knapp.[6])

G. F. Wislicenus.[7] The writer has had the good fortune to witness at close range part of the research work which has been reported by the authors and later has been able to observe how grateful the pump industry is for investigations of this type. This industry has been puzzled for considerable time about mechanical failures of centrifugal pumps such as broken shafts and excessive wear on stuffing boxes and wearing rings. In most of these cases it becomes apparent that the pump was operated under conditions which, according to results obtained at the laboratory of California Institute of Technology, would yield high unbalanced forces acting radially on the impeller. The remedy first tried for such conditions was the use of so-called twin volutes, i.e., two volutes starting at 180 deg. from each other. The splitting up of the waterways, however, tended to decrease the efficiency of the pump. The Worthington Pump & Machinery Corporation therefore introduced the principle of staggering volutes of multistage pumps which had the effect of reducing the effective bending moments to such an extent that their influence can be neglected.

This remedy, however, is of course not applicable to single-stage pumps, and it is in connection with the latter type of pumps where the investigations of the California Institute of Technology laboratory can be expected to have a lasting influence on the future designs, because these experiments eventually will yield a reliable basis for the numerical prediction of the magnitude and direction of such forces.

At the present time the problem of these forces appears to be the most important, but by no means the only one, for which the designer hopes to obtain an answer from the investigations at the California Institute of Technology. The velocity distribution in the volute is of much more general importance, and up to now the designer has been forced to make certain assumptions concerning this matter, the hypothetical character of which could not be doubted since the present state of hydrodynamics does not allow describing the flow conditions in a centrifugal pump by theoretical means. For example, it would seem very desirable to extend the investigations so as to cover the velocity distribution in radial sections through the volute as a function of the rate of discharge.

It is safe to say that the work described in the two preceding papers,[1,6] if considered as a whole, constitutes a complete

[5] "Fundamental Research on the Distribution of Water Pressure in a Centrifugal Pump Impeller," by S. Uchimaru, *The Journal of the Faculty of Engineering*, Tokyo Imperial University, Tokyo, Japan, vol. 16, no. 6, September, 1925, p. 157.

[6] "The Hydraulic-Machinery Laboratory at the California Institute of Technology," by R. T. Knapp, Trans. A.S.M.E., vol. 58, November, 1936, paper HYD-58-5, p. 663.

[7] Worthington Pump & Machinery Corp., Harrison, N. J. Jun. A.S.M.E.

success, and it is only to be hoped that it is but the beginning of further investigations of the same type. It is exactly this kind of research work which is most urgently needed by the designer, referring this time particularly to the increased accuracy of pump tests of the usual kind which reveal facts not detectable by ordinary test-stand experiments. Merely as an example the writer should like to call attention to the possibility of distinguishing clearly between the very first beginning of cavitation and the final cavitation breakdown. Furthermore, it is to be expected that many phases of the technique of measurement, as well as control of operating conditions which were newly developed at the California Institute of Technology, will serve as precedent for future developments in scientific as well as commercial test-stand practice.

Authors' Closure

The authors find it difficult to accept all of Dr. Stepanoff's alternate explanations of the experimental observations. In the first place, they fail to see the force of the argument tending to show the impossibility of a contribution to the useful work of the pump from the flow in the clearance spaces between the impeller and the case. For example, if a balance is made of the energy in the flow entering and leaving the clearance spaces across the cylindrical surface which passes through the measuring-tube stations, it will be found that the energy content of the outflow is greater than that of the inflow. Therefore, the conclusion appears inevitable that energy is delivered to the volute from these clearance spaces, irrespective of the previous history of the fluid which serves as the energy carrier. The authors do not intend to imply that this energy contribution to the volute is equal to that imparted by the impeller shrouds to the fluid in the clearance spaces, but merely wish to suggest that a small part of it may be delivered to the volute instead of being dissipated in friction within the clearance spaces themselves. Thus, as Dr. Stepanoff points out, the circulation of the fluid in these spaces must result in a net loss of energy. He has also called attention to several reasons why modern pumps with larger clearances have higher efficiencies. The authors simply propose that the circulation in the clearance spaces makes one additional contribution to this improvement.

Dr. Stepanoff refers to Le Conte's[3] and Gibson's[4] tests to show that the disk-friction loss itself should be greater with larger clearances. The authors feel that there is a possibility of a fallacy in the extrapolation of these tests to the performance of an actual centrifugal pump. In the disk-friction tests there is no possibility of utilizing any of the energy imparted to the fluid by the disk; therefore, it is all loss. In a centrifugal pump this is not necessarily so, since some of it may be converted to pressure energy in the volute. In this connection, it should not be forgotten that there are two steps necessary in the phenomenon of disk friction: First, the imparting of kinetic energy to the fluid by the rotating disk; and, second, the transformation of this mechanical energy into heat through fluid friction.

It would be easier to accept the writer's explanation of the double peak velocity distribution as its sole cause if it were not for the fact that the phenomenon apparently extends over a width greater than that of the impeller discharge, thus indicating that some of the flow must come from the clearance spaces. Also a detailed consideration of the relative exit angles show their distribution to be quite different from that which would be caused by a superimposed circulation within the impeller. On the other hand, there is no reason to suppose that this possible impeller circulation does not contribute substantially to the peaked distribution observed.

The authors agree with Dr. Stepanoff that the relatively uniform velocity distributions between the impeller vanes shown in Figs. 10 and 14 of the paper seemed improbable before the measurements were made. On the other hand, if all due allowance is made for possible experimental inaccuracies, it is still necessary to conclude that the velocity is comparatively constant during the time required for one impeller passage to pass a given measuring station. Dr. Stepanoff is particularly concerned by this condition for low-capacity conditions during which, as he states, a considerable portion of the power input is wasted in turbulence. The authors believe that if the indications of Fig. 18 of the paper are considered, the tremendous variation in flow in a given passage during one complete revolution will offer ample opportunity to dissipate the necessary amount of energy. They also believe that this variation of velocity with position must be taken into account when the experimental evidence of impeller pitting, wear marks, and pressure-distribution tests within the impeller channels are evaluated.

The authors agree with Dr. Wislicenus that it would be highly desirable to have available more extensive investigations on the velocity distribution in the volute and it is definitely planned to extend this work in the near future. It is felt that much remains to be done before the flow conditions in centrifugal pumps and tubines will be completely understood, and it is hoped that this laboratory will be of service in this field of hydrodynamics.

The Hydraulic-Machinery Laboratory at the California Institute of Technology[1]

Ed S. Smith, Jr.[2] The writer personally witnessed the operation of instruments in the laboratory described by the author. He congratulates all sharing the responsibility for the development of the laboratory and for having created a unique tool of unparalleled accuracy for its highly specialized purpose. It is urged that this same group create a second and smaller laboratory of similar design, but make it one that could be adapted to general rather than specialized use. Such a laboratory would be invaluable to industry as well as for research, but, to be of greatest usefulness, it should be located more centrally (with regard to industry) in the country. Its relatively small cost could be liquidated within a reasonable period.

A small dynamometer, say 50-hp rating, would be suitable for testing the more common sizes of pumps, hydraulic motors, and complete hydraulic power-transmission units, using a moderately viscous oil as the hydraulic medium. The cost of instruments should also be comparatively small since they would be substantial duplicates of those already developed. Such a laboratory would be especially useful for providing the data needed on power-transmission units having pumps or hydraulic motors of the rotary-piston, or gear, type.

These extremely flexible and efficient hydraulic power-transmission units occupy a key position in industry by bridging the gap between the efficient but continuously running, constant-speed a-c motor and equipment that must operate either at variable speeds or intermittently; they are used for presses, elevators, machine-tool drives, rudder controls, and servomotor drives generally, as well as for transporting the fluids themselves.

Although the overall efficiencies of hydraulic power-transmission units with modern pumps or hydraulic motors of the rotary-piston type are readily established or checked by field tests, it is the writer's belief that there are wide differences between the

[1] Published as paper HYD-58-5, by R. T. Knapp, in the November, 1936, issue of the A.S.M.E. Transactions.

[2] Hydraulic Engineer, C. J. Tagliabue Manufacturing Company, Brooklyn, N. Y. Mem. A.S.M.E.

relative efficiencies of pumps and hydraulic motors reported by various manufacturers; some reporting higher pump than motor efficiencies and others vice versa. While there is evident reason for a lower efficiency of a gear-type hydraulic motor than for the same unit used as a pump, this does not seem to justify the present reported differences between pump and motor with modern rotary-piston units making liberal use of antifriction bearings. From tests within the writer's experience, he considers that the probable cause of these discrepancies is the use of Bourdon-type pressure gages on such tests. These are generally chosen with a low enough maximum to give an open scale that facilitates accurate reading during the test period. With such a low maximum, gages are unduly sensitive to the continuous and high-frequency pressure pulsations inherent in these high-speed high-pressure piston-type units. Such gages are also as likely to be thrown out of calibration by severe shocks from surges when changing speeds as when starting and stopping. Since the use of pulsation-throttling devices may cause inaccurate gage indications, it seems necessary to use a gage, if of the Bourdon type, having a scale maximum of from two to three times the normal working pressure to be reasonably sure of having the initial gage calibration maintained during any test of reasonable duration. Also, the sturdier gage made for higher pressures is generally needed to stand the usually severe mechanical vibrations existing in such high-pressure transmissions. Even with such gages it is desirable to remove the stop peg at the scale zero or to shorten the hand enough so that it clears the peg when pressure suddenly drops from a high value.

Pressure-weighing scales, such as those in the laboratory at the California Institute of Technology, promise to make possible, perhaps for the first time, reliable and accurate tests of mechanical efficiencies of rotary-piston pumps and hydraulic motors. The equipment in the proposed laboratory should be built for working pressures up to at least 3000 lb per sq in., and have means for accurately measuring the heat removal necessary to maintain hydraulic power-transmission units at predetermined temperatures. It should also include the accessory instruments for determining precisely the pertinent physical properties of the hydraulic medium under actual working conditions.

Fig. 29 of the paper presents coefficients for a nonstandard venturi meter that would raise a question as to the absolute accuracy of results obtained in this laboratory were it not for the decidedly unconventional nozzle forms used in the approach section and the lack of straightening vanes and/or other means upstream of the tube to insure normal turbulence and velocity distribution, especially at lower values of the Reynolds number. Pitot traverses are indicated. Incidentally, (1) is this Reynolds number based on the conditions at the inlet or throat of the tube? (2) Is not the coefficient of the figure actually the product of the friction coefficient (customarily used) by the correction for the approach velocity? Offhand, it would seem desirable to increase the surface roughness of the approach to the throat enough to obtain a flat coefficient over the range of Reynolds numbers shown in Fig. 14 of the paper, a modification that decreases the error due to any flow abnormality likely to occur in this installation. In this connection, it may be remarked that the spread of coefficients for a given venturi tube is generally less than for other differential producers.

Author's Closure

The author agrees with Mr. Smith that much inaccuracy in pump tests of all kinds is due to the use of Bourdon-type pressure gages. It is the author's opinion that a definite step forward will be made in the moderate-pressure and high-pressure fields by the adoption of the pressure-weighing technique in all research investigation where it is at all practicable.

Mr. Smith calls attention to the unusual calibration curve shown in Fig. 29 of the paper for the 12-in. venturi meter and states that if it were not for the decidedly unconventional construction this would throw a question on the absolute accuracy of the laboratory results. In this regard the author again wishes to point out that the venturi meters were not the primary standards of quantity measurement for the laboratory. This rôle was taken by the volumetric measuring tanks. Their accuracy is not open to question. The venturi meters were frequently calibrated in place and thus furnish reliable working standards. The Reynolds number used in Fig. 29 of the paper is based on the conditions at the throat of the tube, and the coefficient is c in the equation

$$q = cA_2 \sqrt{\left(\frac{2gh}{1 - (A_2/A_1)^2}\right)}$$

where A_2 is the cross-sectional area at the throat, sq ft; A_1 is the cross-sectional area at the upstream piezometer; h is the differential head, ft of water; q is the discharge, cfs; and c is the venturi coefficient of discharge.

In conclusion, the author would take issue with Mr. Smith's remark that the laboratory is "highly specialized." The author feels that this as a misconception of the laboratory possibilities. It is certainly true that up to the present the work has been of a highly specialized nature, but in the closing paragraphs of the paper the author tried to point out the wide scope of investigations possible in the future by means of the use of the laboratory equipment now available.

A Study of Cutting Fluids Applied to the Turning of Monel Metal[1]

Maurice Reswick.[2] In paragraph 6 of the conclusions, the authors state that the emulsion is entirely satisfactory as a cutting fluid for turning monel metal. A large portion of machine work on monel metal is done on automatic screw machines, and it has been the experience of most shops that emulsified oils produce excessive gumming which interferes with the proper operation of these machines. The use of sulphurized mineral oils on such machines is therefore a necessity, notwithstanding their tendency to stain the metal. It would be of much interest to see a curve showing the relation between cutting speed and tool life based on turning monel metal using mineral oil compounded with fats, such as lard oil, for the cutting fluid. Such cutting oils, although less efficient than sulphurized oils from the standpoint of tool life, have an advantage in that they do not stain the metal and usually produce a finer surface finish.

From former experiments performed by Professor Boston and his associates on S.A.E. 3140 steel, it appears that tool life increases progressively with the three types of cutting fluids mentioned in the following order: Mineral oil compounded with fats, soluble oils, and sulphurized mineral oils. From the standpoint of surface finish, mineral oils compounded with fats come first, sulphurized oils second, and soluble oils last. No doubt the same general conclusions apply to monel metal.

In paragraph 8 of the conclusions, referring to Fig. 6 of the paper, it is pointed out that all component cutting forces are higher when water emulsions are used as the cutting fluid than for sulphurized mineral oil, indicating that the power consumption of the machine, and therefore the heat generated at the point of

[1] Published as paper MSP-58-10, by O. W. Boston and W. W. Gilbert, in the November, 1936, issue of the A.S.M.E. Transactions.

[2] Lubrication Engineer, Standard Oil Company of New Jersey, New York, N. Y. Mem. A.S.M.E.

the tool, is greater with soluble oils. The satisfactory tool-life obtained in the tests with water emulsions is evidently due to the greater cooling action of the oil-in-water emulsion.

The criterion established by Professor Boston to evaluate the relative efficiencies of cutting fluids and machinability of metals in terms of cutting speed versus tool life is, in the writer's opinion, the closest approach yet attained in reproducing actual machine-shop conditions on a laboratory scale. As yet, however, the results of these experiments should be considered as being indicative only, since they are carried out under carefully controlled laboratory conditions, with most of the disturbing factors met in the average machine shop eliminated. Performance under actual conditions in each particular instance still remains the final proof of merit of cutting fluids.

Joseph Geschelin.[3] This paper is important not only because of its influence upon the machining of monel metal but in the broader sense because is contributes still another link in the fundamental research on the utilization of cutting fluids as well as on the design of cutting tools.

Despite the good work of the A.S.M.E. Subcommittee on Cutting Fluids, there still remains considerable work to be done in drawing attention of all metal-cutting establishments to the importance of the proper selection and utilization of cutting fluids. The larger establishments are conscious of the problem and are working on it constantly; although, even in these establishments there is room for progress.

Viewed broadly, the utilization of cutting fluids should proceed along two parallel lines—one, the immediate commercial development which must be carried on to satisfy the needs of metal-cutting establishments, and two, a definite program of fundamental research. The latter has been ably handled by Professor Boston and his associates, and it is hoped that he will be able to carry this work to a definite conclusion.

Authors' Closure

Mr. Reswick raises a question as to the proper cutting fluid for machining monel metal in an automatic screw machine. The authors stated in the paper that for the proper shape of cut, that is, a deep thin cut, an emulsion will give a higher cutting speed for a given tool life than the sulphurized mineral oil or dry cutting. Even for a comparatively shallow thick shape, the emulsions are superior to the sulphurized mineral oil when cutting at comparatively low speeds to give a tool life above 30 min. It was pointed out, however, that in turning the monel metal with a single-point tool the sulphurized mineral oil caused the chips to break up more satisfactorily, which is an advantage, but that the monel metal was stained by sulphur in the oil, which is a disadvantage.

[3] Detroit Technical Editor, Chilton Company, Detroit, Mich.

Naturally, if an automatic screw machine were to be used, presumably not only the lubrication of the machine, but in addition the types of cuts should be considered. Tapping and threading are usually done in this class of work, and the material is turned with forming tools. These are questions quite outside the scope of the paper. It would seem advisable, however, to use the sulphurized mineral oil in view of the threading, the lubrication, and the satisfactory operation of the forming tools. The authors are not in a position to furnish Mr. Reswick with an additional cutting-speed tool-life curve in which a mineral oil compounded with fats, such as lard oil, is used. As stated in the paper, there was insufficient material available to carry on more tests than those that are actually covered in the report.

Mr. Reswick raises the question as to the influence of the cutting fluid on finish, referring to results previously obtained when turning an S.A.E. 3140 steel. The authors feel that in turning cuts the finish on the work is influenced in only a small way by the cutting fluid used. Material is being accumulated along this line, and it will be the subject of a paper to be written in the near future. To secure finish, the items essential are (1) a small-size cut, (2) a tool with high rake, (3) high cutting speed, and (4) an appropriate cutting fluid. The authors believe that the cutting fluid itself has the least influence. Naturally, where low speeds are encountered, as in threading and reaming, factors other than speed become of greater importance.

Mr. Reswick has also raised the question of power versus tool life. The authors have found that, as a result of a wide variety of tests, the value of cutting force, when using a given cutting fluid, is not a satisfactory basis to predict tool life when using the same cutting fluid. In some instances it has been found that the cutting speed for a given tool life, under otherwise constant conditions, varied directly as the cutting force. That is, when the cutting force is highest for a given set of oils, the cutting speed for a given tool life is also highest. This is just the opposite of what might be expected. At the same time data are available for specific cases which show the cutting speed for a given tool life to vary inversely with the cutting force. The interrelation of finish, cutting force, and tool life is naturally of great interest to one engaged in metal-cutting operations. There appears to be no consistent relation between any two of the three. Undoubtedly, a great deal of research work still must be done to solve the riddle and thereby make it possible to predetermine cutting conditions to give the most satisfactory results.

As Mr. Geschelin points out, fundamental research and commercial practice should go hand in hand. It is believed that the commercial use of cutting fluids can be improved to a very great extent by the accumulation of fundamental data relating to the selection and application of cutting fluids.
